THESIS

Submitted as partial fulfillment of the requirements
for the degree of Doctor of Philosophy in Physics
in the Graduate College of the
University of Illinois at Chicago, 2005

Chicago, Illinois

To Dasha

ACKNOWLEDGMENTS

First, I wish to thank my thesis advisor, Nikos Varelas, who guided and supported me throughout the years. Thanks to the other members of the UIC group at DØ - Mark Adams, Cecilia Gerber, and Elizaveta Shabalina - for their assistance. Special thanks to Alan Stone for his help.

I am also indebted to many people in the Higgs Group at DØ ; to the Higgs group conveners Gregorio Bernardi, and Avto Kharchilava; to Kazu Hanagaki, who taught me to never surrender; to Jodi Wittlin, who tried to convince me that Higgs bosons are red. I would especially like to thank Suyong Choi for his help and advice.

I was lucky to work on the trigger system alongside Adam, Burair, Josh K., Miroslav, and Terry T.

Of course, this work would not have been possible without the help and support from the hard working DØ Collaboration (see Appendix A).

On a more personal note, I would like to thank the friends who kept me sane over the course of these years; Reinhard, the fastest postdoc at DØ , and Bob H., who showed me the artsy side of Chicago; Juan and Kyle, for being such good friends; Paul and Randal, for stimulating discussions about particle physics and beyond; Aneta and Richard, for helping me find my way through the jungle of UIC thesis regulations; and Jui, for her perfect assistance as UIC graduate adviser.

I could not have survived without support from the UIC "gang". Thanks Gustavo, James,

ACKNOWLEDGMENTS (Continued)

and Tim, for some unforgettable moments. Special thanks to Mario for introducing me to the insanely fine art of Espresso.

Mom and dad, thank you for your patience and support, while I was pursuing my studies far away from home. Thanks to Anja, for being a great sister.

Finally, I would like to thank Dasha for her love. This dissertation would not have been possible without her encouragement.

SUMMARY

We present a study of events with Z bosons and hadronic jets produced at the Tevatron in $p\bar{p}$ collisions at a center of mass energy of 1.96 TeV. The data consist of approximately 14,000 $Z/\gamma^* \to e^+e^-$ decay candidates from 343 pb^{-1} of integrated luminosity collected using the DØ detector. Cross sections and jet production properties have been measured for $Z/\gamma^* + \geq 0$ to 5 jet events. We find our results to be in good agreement with QCD predictions.

CHAPTER 1

INTRODUCTION

Since the discovery of the Z boson at CERN in 1983 (1; 2), the production of electroweak gauge bosons in association with jets has been of increasing importance. A measurement of the $Z+ \geq n$ jet cross sections provides a good test for our understanding of quantum chromo dynamics (QCD). In addition, hadronic production of the Z boson is a major background to many interesting physics processes. In particular, searches in the channel where a Higgs boson is being produced in association with a Z boson rely on a detailed understanding of the $Z+ \geq n$ jet background.

Chapter 2 of this dissertation provides a short overview of the theoretical framework within which this analysis was performed. A description of the experimental apparatus, including the Fermilab chain of accelerators, and the DØ detector is given in Chapter 3. Chapter 4 describes the methods that are used to reconstruct physical objects from raw detector data. The Monte Carlo (MC) event generators that are used are illustrated in Chapter 5. We describe the data and MC samples, including comparisons between data and MC, in Chapter 6. Chapters 7 and 8 outline all steps that lead to the measurements of the inclusive $Z/\gamma^*(\to e^+e^-)$ and $Z/\gamma^*(\to e^+e^-)+ \geq n$ jet cross sections. Sources for systematic uncertainties are discussed in Chapter 9. A brief summary of the final results, together with a discussion of future plans, is given in Chapter 10.

Throughout this dissertation (unless stated otherwise) we follow the customary convention by which $\hbar = c = 1$.

CHAPTER 2

THEORY

2.1 <u>The Standard Model</u>

The *Standard Model (SM) of Particle Physics* is the name given to the current theory of elementary particles and the forces that act between them. It is a quantum theory of fields (QFT), which arises when combining quantum mechanics with special relativity. The SM includes most of our current understanding of the laws of physics (except gravity), and has been verified experimentally to an extremely high level of accuracy.

Nevertheless, the theory is incomplete. The SM contains many free parameters that cannot be derived from first principles. The Higgs boson, which is considered to be the last remaining piece to the SM, has not been experimentally detected yet. Most importantly, gravity is not included in the SM. A framework that consistently combines quantum mechanics with general relativity into a theory of *quantum gravity* has not been discovered yet.

The following is a brief overview of the SM, together with the particles and interactions that it describes (3; 4; 5; 6; 7; 8; 9).

2.1.1 <u>Quarks and Leptons</u>

In the SM the most fundamental particles that make up ordinary matter are divided into two groups: *quarks* and *leptons* (Figure 1, Reference (10)). Both quarks and leptons are *fermions* since they are spin-$\frac{1}{2}$ particles, and therefore obey Fermi-Dirac statistics. As indicated in

Figure 1, quarks and leptons are each arranged in three families, each family being identical except for the masses of its members. For each particle there exists an anti-particle with opposite charge.

There are six different flavors of quarks, labeled (in order of increasing mass) *up*, *down*, *strange*, *charm*, *bottom*, and *top*. It is remarkable to note that quarks are never observed as single particles (see Chapter 2.1.2.3), and that they carry fractional electrical charges[1] of $+\frac{2}{3}$ or $-\frac{1}{3}$. Quarks form bound states called *hadrons* by either combining three quarks into *baryons*, or by pairing a quark with an antiquark into *mesons*. Protons (made up of two up-quarks and one down-quark) and neutrons (made up of two down-quarks and one up-quark) are the most common examples of baryons. Pions ($\pi^{0,\pm}$) and Kaons ($K^{\pm}$, K^0, $\bar{K}^0$) are the most common type for mesons.

There are three different flavors of charged leptons, carrying a charge of -1: *electrons* (e^-), *muons* (μ^-), and *taus* (τ^-). While electrons exist in all atoms, muons and taus can only be observed in energetic processes like cosmic ray showers, or high energy particle collisions. There are three neutral leptons, called *neutrinos* (ν), each corresponding to a charged lepton: ν_e, ν_μ, and ν_τ. Neutrinos interact extraordinarily weakly with matter, and their masses are negligibly small.

---

[1] All charges are given in units of the absolute value of the electron charge, 1.602×10^{-19} Coulombs.

Leptons spin = 1/2				**Quarks** spin = 1/2		
Flavor	Mass GeV/c^2	Electric charge		Flavor	Approx. Mass GeV/c^2	Electric charge
ν_e electron neutrino	$<1\times10^{-8}$	0		u up	0.003	2/3

τ tau	1.7771	−1		b bottom	4.3	−1/3

Figure 1. Quarks and leptons.

2.1.2   Interactions

One of the most fundamental insights in theoretical physics is that interactions are dictated by symmetry principles. In QFT interactions manifest themselves by imposing symmetry conditions on the quantum fields representing the respective interactions. Using the framework of Lagrangian field theory, we require that the Lagrangian of the theory be invariant under a group of local phase changes (*local gauge invariance*). A local phase depends on space and time in a completely arbitrary way. The Lagrangian is no longer invariant under such local phase changes. In order to preserve gauge invariance of the Lagrangian (on purely aesthetic grounds), we introduce an additional gauge field. Excitations of these gauge fields lead to force-carrying spin-1 bosons that mediate the interactions of nature.

Four types of interactions are currently known (in order of decreasing strength): strong, electromagnetic, weak, and gravitational. Figure 2 summarizes basic properties of the four interactions (10). Note that gravity has not been incorporated into the SM, since no QFT for gravitational interactions has been discovered yet. Additionally, gravity is simply too weak to have any significant influence on particle interactions.

QFT uses the tools of *perturbation theory*. Physical quantities like cross sections cannot be computed exactly, but they can be approximated to a high precision. In practice, calculations are performed by drawing *Feynman diagrams*, which are graphical representations of the processes under consideration. As an example, Figure 3(a) and Figure 3(b) show two Feynman diagrams describing electron-positron annihilation with subsequent muon-antimuon pair production, $e^+e^- \to \gamma^* \to \mu^+\mu^-$. Both diagrams have the same initial and final state con-

figuration. While Figure 3(a) shows the lowest order (*tree level*) diagram, Figure 3(b) has an additional photon loop connecting the final state muon-antimuon lines (*one-loop correction*). An infinite amount of higher order diagrams with additional loop corrections exists, and a full calculation would have to take into account all of these diagrams. Every additional loop introduces additional factors of the coupling constant of the interaction. The physical quantity that needs to be evaluated based on these diagrams therefore forms a power series with successive terms containing higher powers of the coupling constant. If the coupling constant is small, higher order contributions become negligible, and the power series converges.

An additional problem arises from the fact that all possible energy-momentum values of the virtual loop particles must be considered as well. This can lead to infinities in the calculations, i.e. the final result is non-physical. The concept of *renormalization* solves this problem at a practical level. As an example, consider the electrical charge of the electron. Taking higher order loop diagrams into account, the power series evaluating the charge diverges. The idea behind renormalization assumes that the electric charge that is actually observed is the sum of the *bare* charge (due to the tree level process) plus the contributions of all higher order diagrams. We then assume a value for the bare charge that is infinite as well, but opposite to that part of the higher order corrections. In other words, the two infinite contributions cancel each other to yield the finite, experimentally observed result for the electrical charge of the electron. If for a given theory all infinities can be absorbed into the available free parameters, the theory is considered *renormalizable.*

Technically, in order to express a physical parameter like the electron charge in terms of the

Property \ Interaction	Gravitational	Weak (Electroweak)	Electromagnetic	Strong	
				Fundamental	Residual
Acts on:	Mass – Energy	Flavor	Electric Charge	Color Charge	See Residual Strong Interaction Note

Figure 2. Fundamental forces and their properties.

bare parameter, the introduction of an arbitrary scale called the *renormalization scale* (μ_R), is required. It is customary to set μ_R equal to the typical energy scale associated with the process of interest. Different choices for μ_R represent different *renormalization schemes*. The renormalization scale essentially removes physics beyond $\frac{1}{\mu_R}$ from perturbative calculations, including diverging loop corrections and interesting short distance physics (quantum gravity). The coupling constant of the interaction and the coefficients of the perturbative expansions become a function of μ_R, although ultimately (calculating them to infinite orders) they are independent of μ_R. One can exploit this fact to calculate the effective variation of physical constants with changes in scale, also known as the *renormalization group*.

The following is a brief summary of the interactions that have been incorporated into the SM.
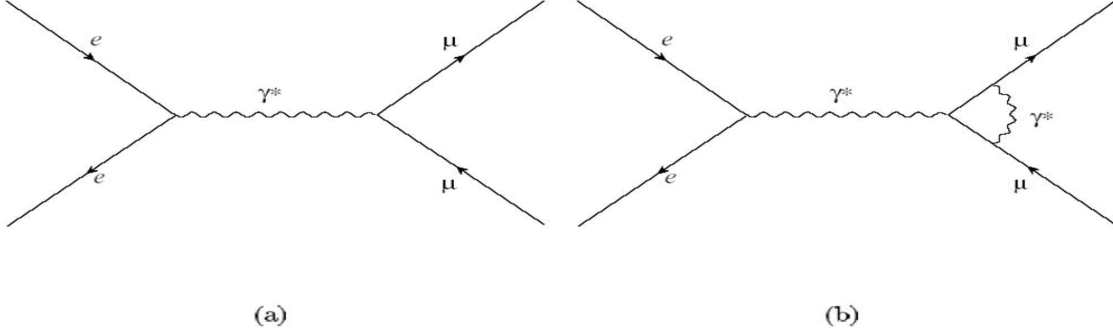

Figure 3. Feynman diagram for the process $e^+e^- \rightarrow \gamma^* \rightarrow \mu+\mu-$. (a) Tree level diagram. (b) One-loop diagram.

2.1.2.1 Electromagnetic Interaction

Historically, the electromagnetic interaction was the first to be formulated in the framework of a renormalizable QFT by Tomonaga, Feynman, and Schwinger in the 1940s (Nobel Prize in 1965). All subsequent efforts to create theories for other interactions are modeled on it. *Quantum Electrodynamics* (QED) describes the electromagnetic interaction by requiring gauge invariance under U(1) group transformations. U(1) denotes a group of unitary one-dimensional matrices, describing space-time dependent rotations in a complex plane. The requirement of gauge invariance gives rise to the photon field and the *photons* as the corresponding mediator of the electromagnetic interaction. Because the photon is massless the interaction is long range. The photon couples to all particles that carry electrical charge, like quarks and charged leptons.

The strength of the coupling is proportional to the magnitude of the dimensionless *fine structure coupling constant*:

$$\alpha_{EM} = \frac{e^2}{4\pi} \approx \frac{1}{137} \tag{2.1}$$

2.1.2.2 <u>Weak Interaction</u>

The weak interaction is most prominent in *beta decays* (Equation 2.2 and Equation 2.3) and associated radioactivity.

$$n \rightarrow p + e^- + \bar{\nu}_e \tag{2.2}$$

$$p \rightarrow n + e^+ + \nu_e \tag{2.3}$$

The range of the interaction is short due to the high mass of the mediating gauge bosons ($W^\pm$, Z^0):

$$m_{W^\pm} \approx 80 \; GeV \tag{2.4}$$

$$m_{Z^0} \approx 91 \; GeV \tag{2.5}$$

A QFT combining the electromagnetic with the weak interaction was first developed by Glashow, Weinberg, and Salam (*GWS theory*, Noble Prize in 1979). Later 't Hooft and Veltman were able to prove that the theory is renormalizable (Nobel Prize in 1999). Electroweak theory combines a new U(1) group with an SU(2) group, and requires invariance under SU(2)⊗U(1) transformations. SU(n) describes groups of special[1] and unitary $n \times n$ matrices. Local gauge

---

[1]The determinant of the matrices must be 1.

invariance under SU(2) group transformations introduces three massless spin-1 gauge bosons W^+, W^-, and W^0. Adding the U(1) group introduces another gauge boson called B^0. The W^0 and B^0 mix quantum mechanically to give rise to the experimentally observed photon (γ) and Z^0:

$$\gamma = W^0 \sin\theta_W + B^0 \cos\theta_W \tag{2.6}$$

$$Z^0 = W^0 \cos\theta_W - B^0 \sin\theta_W \tag{2.7}$$

where θ_W is called the *weak mixing angle* or *Weinberg angle*. As opposed to QED, the underlying group of the electroweak theory is *non-Abelian* since not all the generators of the group commute with each other. This ultimately leads to self interaction between the gauge bosons.

Up to this point the electroweak theory is very simple and elegant. Yet it is incomplete, since all gauge bosons of the theory are massless. However, we know from experiment that the W and Z bosons are heavy (Equation 2.4 and Equation 2.5). Additionally, mass terms cannot be introduced into the Lagrangian describing the system, since this generates unrenormalizable divergences which make the theory unphysical. This problem is resolved by a process known as *electroweak symmetry breaking*.

Electroweak symmetry breaking is achieved by introducing a new field, the Higgs field Φ, where Φ is an SU(2) doublet of complex scalar fields:

$$\Phi = \begin{pmatrix} \Phi^+ \\ \Phi^0 \end{pmatrix} \tag{2.8}$$

The simplest and most general Lagrangian for the Higgs field, consistent with SU(2) gauge symmetry, is:

$$\mathcal{L}_{Higgs} = (\partial_\mu \Phi)^\dagger (\partial^\mu \Phi) - \mu^2 \Phi^\dagger \Phi - \lambda(\Phi^\dagger \Phi)^2 \tag{2.9}$$

where the first term contains the Higgs field kinetic energy and gauge interactions, and the remaining terms describe the Higgs potential (Figure 4). SU(2) symmetry is spontaneously broken by requiring that the minimum of the Higgs potential lies not at zero, but on a circle of minima:

$$\langle\, \Phi^0 \,\rangle = \frac{\mu}{\sqrt{2\lambda}} = \frac{v}{\sqrt{2}} \tag{2.10}$$

where v is the Higgs field vacuum expectation value, $v \approx 246$ GeV. Replacing Φ in Equation 2.9 with $\Phi = (0, v/\sqrt{2})$, results in the W and Z bosons acquiring mass through interaction with the Higgs field.

Excitations of the Higgs field give rise to a particle known as the *Higgs boson*. The mass of the Higgs boson is not known, and the particle has not yet been observed experimentally.

2.1.2.3   Strong Interaction

Quantum Chromo Dynamics (QCD) is the QFT describing the strong interaction. It is based on an SU(3) gauge field, which leads to 8 mediating massless gauge bosons called *gluons*. Strongly interacting particles like quarks and gluons carry a new type of charge called *color*. Each (anti)quark can carry a (anti)red, (anti)green, or (anti)blue color charge. Gluons carry a combination of a color and anticolor charge. The fact that gluons are themselves carriers of the color charge allows them to couple to each other. This essentially derives from the non-Abelian
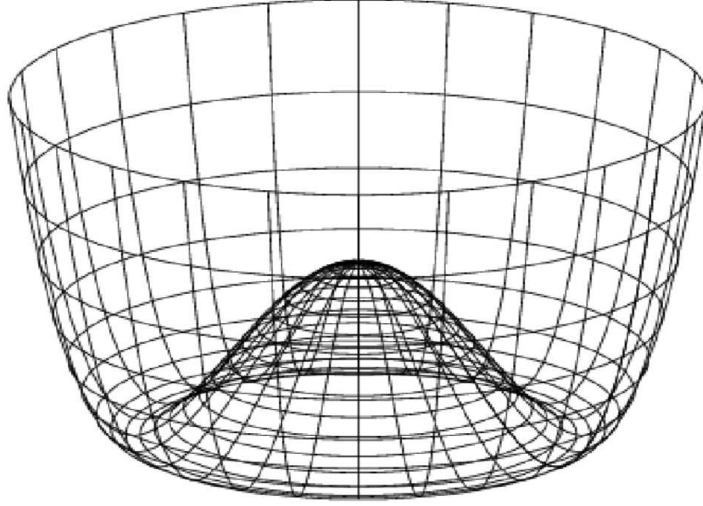

Figure 4. The Higgs potential.

character of the gauge theory. Quarks and gluons are collectively referred to as *partons*.

One interesting feature of QCD is the fact that the strength of the strong coupling increases with decreasing energy scale, i.e. at low energies and long distances the interaction becomes too strong to be treated within the framework of perturbation theory. This leads to the idea of *confinement*, which assumes that all objects carrying color can never be found as free particles in nature and that they are confined into color-neutral composite hadrons. Colors can be combined into color-neutral objects in two ways: a colored quark combined with an antiquark of the corresponding anticolor (meson), or a combination of three (anti)quarks each carrying

a different (anti)color (baryon)[1]. This essentially confines quarks to a small region near one another. The quarks that combine into baryons or mesons are referred to as *valence quarks.* They constantly interact with each other by exchanging gluons. Since gluons can couple to each other, they can emit more gluons that can further split into virtual quark-antiquark pairs called *sea quarks.*

Another important consequence of confinement is the fact that quarks and gluons are observed experimentally as *jets* of color-neutral hadrons. This means that if a single parton emerges from a particle collision, gluons will be radiated which subsequently produce quark-antiquark pairs, which ultimately combine into a jet of hadrons moving in the direction close to that of the original parton. This process is called *hadronization.*

As the energy scale increases, the strength of the strong coupling decreases. This has the consequence that partons behave like free particles at energies that are typical of modern high-energy experiments. This is called *asymptotic freedom.* Theoretical work on asymptotic freedom by Gross, Politzer, and Wilczek was rewarded with the 2004 Nobel Prize.

In practice, when calculating partonic cross sections, perturbative (high energy, small distance) and non-perturbative (low energy, large distance) regions of parameter space are separated in energy by the *factorization scale*, μ_F. The non-perturbative regime is described by *Parton Distribution Functions* (PDF). PDFs parameterize the momentum distributions of partons within the proton and are determined experimentally from deep inelastic scattering

---

[1]Several experiments since 2003 claim to have seen a *pentaquark* which would combine four quarks and one antiquark.

experiments. When calculating cross sections beyond leading orders in perturbation theory, additional loops (*virtual corrections*) and external lines (*real corrections*) need to be included. Higher order corrections will lead to divergences in the soft and collinear limits of parton emission. When calculating fully inclusive quantities, finite results can be obtained since divergences due to the virtual and real corrections cancel. These divergences do not cancel exactly when more exclusive quantities are calculated. Logarithmic terms that become large in the soft and collinear limit need to be treated using a technique known as *resummation*. Leading Logarithmic (LL) terms of the form $(\alpha_s ln)^n$, where α_s is the strong coupling constant, can be summed to all orders in perturbation theory to yield finite results. This is known as the Leading Log Approximation (LLA).

2.2 $\underline{Z/\gamma^* \, (\rightarrow e^+e^-) + \geq n \, \textbf{Jets}}$

The production of Z/γ^* gauge bosons in association with jets of hadronic particles provides a good opportunity to test perturbative QCD predictions at large momentum transfers. Physical quantities in QCD are generally expressed as perturbative expansions in the strong coupling constant by separating processes at different orders of α_s. Figure 5 shows one of the leading-order (LO) processes that produces a Z boson with an associated jet. The decay of the Z/γ^* gauge bosons into pairs of electrons (e^-) and positrons (e^+) provides an efficient way to identify candidate events with low background contamination.

In this analysis we study Z/γ^* gauge boson production and test the reliability of perturbative QCD predictions over a range of jet energies and jet multiplicities. The results are compared to state-of-the-art MC event simulations, representing LO and next-to-leading order
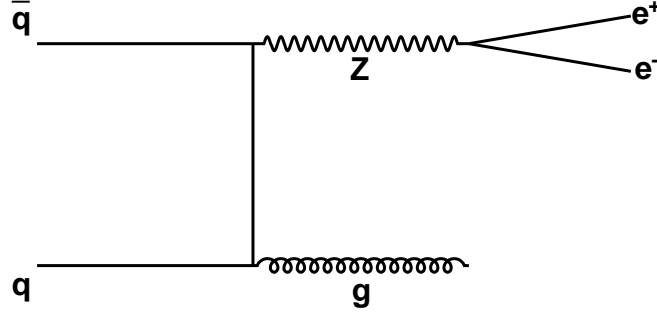

Figure 5. Feynman diagram for one of the leading-order processes that produces a Z boson with an associated jet coming from a gluon.

(NLO) QCD calculations. A description of the MC event generators that were used is given in Chapter 5.

The production of Z/γ^* gauge bosons in association with jets is also an important background process relevant for Higgs boson searches. One of the dominating Higgs production modes at the Tevatron involves the generation of a Higgs boson in association with a Z boson (Figure 6). The study of jet properties and cross sections for processes that generate similar final state particles (Figure 7), allows for a more precise distinction between a possible Higgs signal and QCD background.

The analysis presented in this dissertation was performed with the DØ detector at the Fermilab proton-antiproton Tevatron collider. The following chapter gives an overview of the experimental apparatus that was used for this analysis.
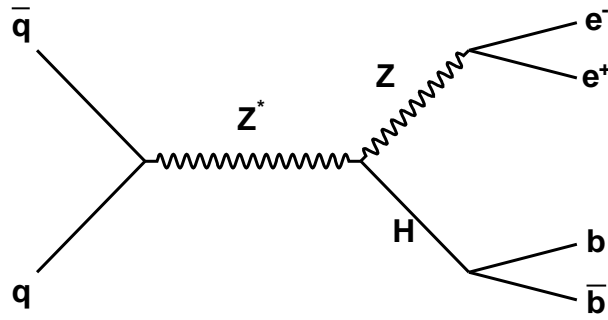

Figure 6. SM Higgs boson production in association with a Z boson (*Higgsstrahlung*).
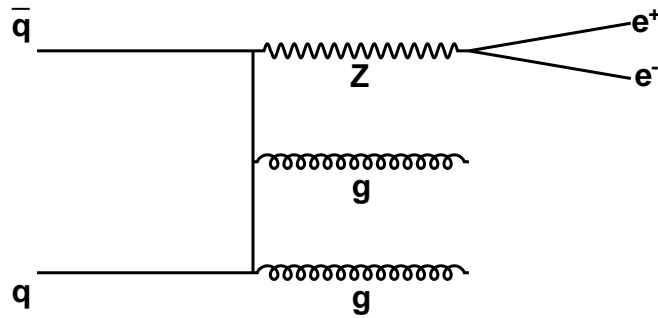

Figure 7. Z boson generation in association with two gluons.

CHAPTER 3

EXPERIMENTAL APPARATUS

The Fermi National Accelerator Laboratory (FNAL, or Fermilab) currently operates the world's highest energy proton-antiproton collider, the *Tevatron*. In this chapter we describe the chain of accelerators that is necessary to achieve a center-of-mass collision energy of 1.96 TeV. We also give an overview of the DØ detector which is built around one of the collision regions where protons and antiprotons collide.

The data used in this analysis was recorded with the DØ detector during the data taking period known as Run II, which officially began in March 2001.

3.1 The Fermilab Accelerators

The Tevatron is the final stage in a sequence of seven accelerators (11; 12; 13). A Cockcroft-Walton *preaccelerator*, a linear accelerator (*Linac*) and a synchrotron (*Booster*) provide a source of 8 GeV protons. The antiproton *Debuncher* and *Accumulator* are two components of the *Antiproton Source*. The *Main Injector* serves as the final boosting stage before injecting protons and antiprotons into the Tevatron. It also provides the necessary source of energetic protons which are needed in the Antiproton Source.

Figure 8 gives an overview of the Fermilab accelerator complex (14).
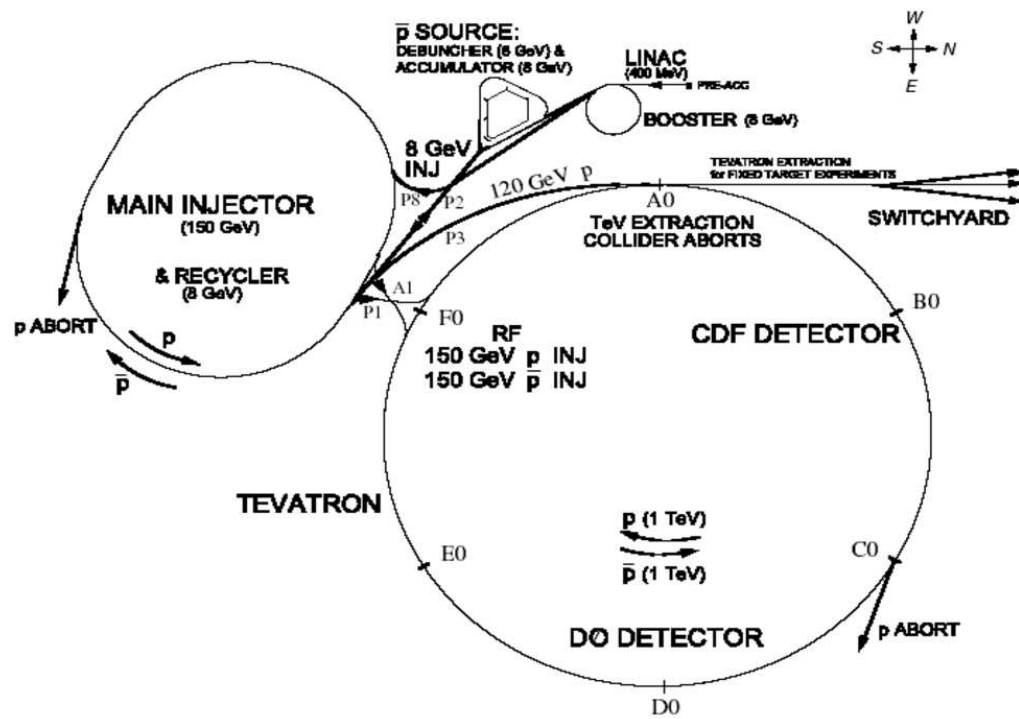

Figure 8. Schematic view of the Fermilab accelerator chain.

3.1.1   The Preaccelerator

The purpose of the preaccelerator is to produce negatively charged hydrogen ions (H^-) with an energy of 750 keV, which are then transfered into the Linac.

Hydrogen gas (H_2) enters a magnetron surface-plasma source (Figure 9, Reference (11)). Due to the electric field between the anode (negatively charged) and cathode (positively charged) the electrons are stripped away from the hydrogen atoms to create a plasma. The positively charged hydrogen ions then strike the surface of the cathode to collect extra electrons and thereby form negatively charged hydrogen ions. The H^- ions are extracted through the anode aperture with an electric field of 18 kV applied by the extractor plate (see Figure 9).

A commercial Cockcroft-Walton Generator produces a 750 kV potential differential by charging capacitors in parallel from an AC voltage source and discharging them in series, via diodes [1]. The Cockcroft-Walton Generator is used to further accelerate the H^- ions to an energy of 750 keV.

After exiting the Cockcroft-Walton device the H^- ions travel through a transfer line. Before entering into the Linac the continuous stream of H^- ions passes through a single gap radio frequency (RF) cavity which bunches the beam at the RF frequency of the Linac (201.24 MHz).

---

[1]The maximum voltage is limited by how much the air can "stand off" before sparking.
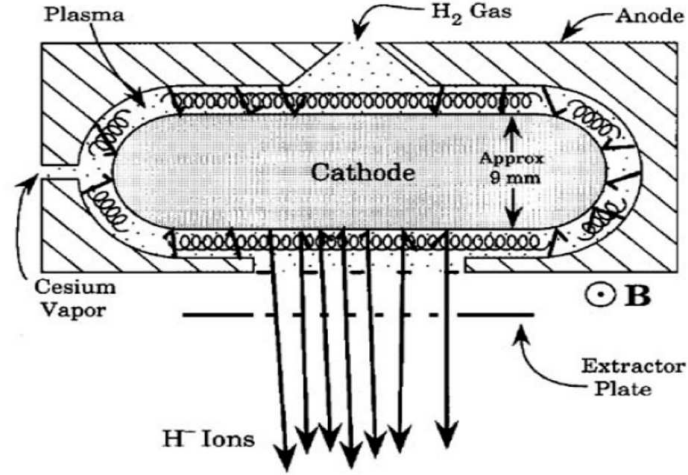

Figure 9. Schematic view of magnetron operation for the hydrogen ion source.

3.1.2   The Linac

The Linac receives bunches of 750 keV H^- ions from the preaccelerator and accelerates them further to an energy of 400 MeV using RF cavities (Figure 10, Reference (11)). The RF cavities are contained within a collection of steel tanks which are holding a sequence of drift tubes separated from each other by gaps. In order to accelerate H^- ions, the cavities are designed in such a way that particles traveling in the gaps experience an acceleration, while particles traveling in the drift tubes are shielded from the RF.

After passing through the Linac, bunches of 400 MeV H^- ions are transfered into the Booster.
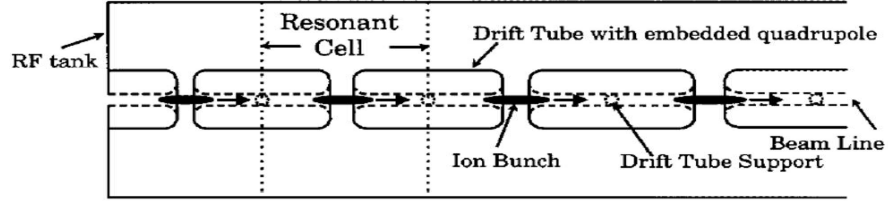

Figure 10. Schematic of Linac RF cavity.

3.1.3   The Booster

The Booster is the first synchrotron in the chain of accelerators. It consists of a sequence of dipole and quadrupole magnets and 17 RF cavities arranged in a circle with a diameter of 151 m. The Booster accelerates protons to an energy of 8 GeV.

It is easier to merge negatively charged H ions coming from the Linac with protons (H^+ ions) circulating in the Booster due to their opposite charge. Therefore the two beams are merged with the help of dipole magnets, and the electrons are stripped from the H^- ions by letting the combined beam pass through a carbon foil.

Once the Booster is filled with proton bunches, the RF cavities provide an acceleration up to 8 GeV. At the same time the field strength in the dipole magnets is adjusted accordingly in order to maintain a constant radius for the circulating particles. Once the protons have reached an energy of 8 GeV they are transfered into the Main Injector.

3.1.4   The Main Injector

The Main Injector is a circular synchrotron with a diameter of 1 km. It can accelerate both protons (coming from the Booster) and antiprotons (coming from the Antiproton Source) from 8 GeV to 150 GeV, before injecting them into the Tevatron. It also delivers 120 GeV protons to the Antiproton Source.

3.1.5   The Antiproton Source

The Antiproton Source consists of three major components: the *Target Station*, the *Debuncher*, and the *Accumulator*. In the first step the Target Station receives 120 GeV protons from the Main Injector and diverts them onto a Nickel Target. This produces a shower of secondary particles (including antiprotons) at many different angles and large spread in particle momentum. A Lithium lens and bending magnets are used to focus the beam and remove positively charged particles (Figure 11, Reference (15)). A process called *stochastic cooling* is used in both the Debuncher and Accumulator in order to reduce the spread in momentum and position of the antiprotons and thereby "cooling" them.

Both the Debuncher and Accumulator are located in a rounded-triangle shaped tunnel with a circumference of about 51 m. Antiprotons coming from the Target Station are transfered into the Debuncher where the momentum spread of the particles is reduced. It is technically very challenging to accumulate a large quantity of antiprotons. On average for every 1 million protons that hit the Nickel target, only about 20 antiprotons can be gathered. Therefore the Accumulator stores antiprotons till a sufficient amount has been generated that can be trans-
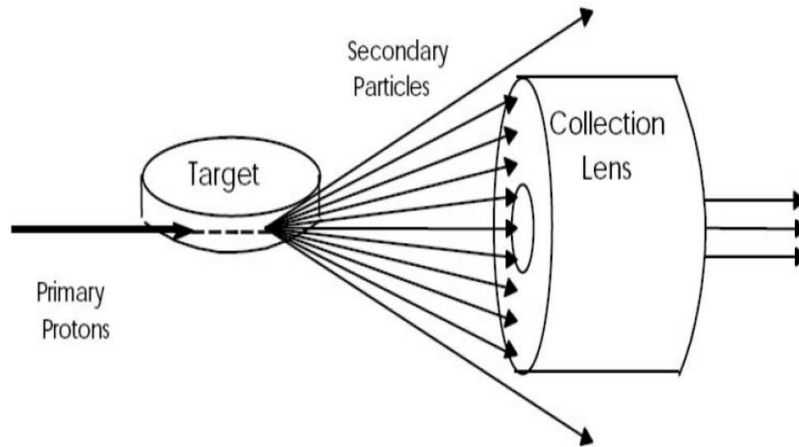

Figure 11. Simplified drawing of anti-proton production with nickel target and lithium lens.

fered into the Main Injector. The Accumulator must be capable of storing antiprotons over many hours.

3.1.6 The Tevatron

The Tevatron is the final stage in the sequence of proton and antiproton acceleration. It has a diameter of 2 km and uses superconducting magnets which operate at liquid helium temperature providing magnetic fields of up to 4 Tesla. Protons and antiprotons are accelerated to 980 GeV, leading to a center-of-mass collision energy of 1.96 TeV.

Protons and antiprotons travel in groups of particles (*bunches*) in opposite directions while sharing the same beam pipe. A full revolution (*turn*) takes $\approx$21 μs. The Tevatron has 1113

RF buckets which are separated from each other by ≈19 ns. Seven RF buckets make up a *tick*, and each tick is separated by ≈132 ns (1 turn has 159 ticks). The Tevatron currently stores 36 bunches of protons and antiprotons. A three fold symmetry is imposed by separating the 36 bunches into three superbunches, with 19 empty ticks between the last bunch in one superbunch, and the first bunch in the next superbunch. Two ticks separate each bunch within a superbunch.

Overall, this leads to a time structure that collides bunches of protons and antiprotons (*bunch crossings* or *zero bias events*) every 396 ns, at three different interaction regions (16).

3.2   Luminosity and Cross Section

Luminosity $\mathcal{L}$ is a measure of the particle flux per unit area and per unit time $(\text{cm}^{-2}\text{s}^{-1})$. In a collider experiment such as DØ, the luminosity gives an indication of how many proton-antiproton collisions (*events*) occur in a given time and area. The luminosity is determined by measuring the rate of inelastic proton-antiproton scatterings (for each tick), which have a known cross section (17; 18).

The cross section σ is a measure of the interaction probability per unit flux. Cross sections are usually expressed in *barns*, where 1 barn $= 10^{24}$ cm^2.

The number of times a given process occurs, N, is proportional to $\mathcal{L}$ and σ:

$$N = \sigma \cdot \int \mathcal{L} \, dt \tag{3.1}$$
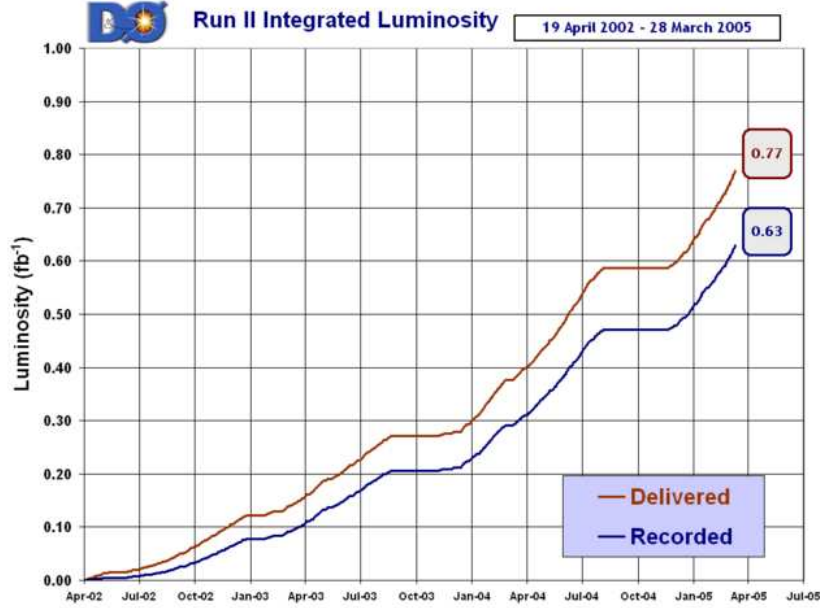

Figure 12. Tevatron integrated luminosity delivered to DØ (April 2002 - March 2005).

$\int \mathcal{L}\, dt$ is called *integrated luminosity*. Figure 12 shows the integrated luminosity profile of the Tevatron, covering the data-taking period from April 2002 till March 2005. A total integrated luminosity of 343 pb^{-1} was used for the result presented in this analysis.

3.3   The DØ Detector

The DØ detector (Figure 13, References (19; 20)) has a magnetic central-tracking system, consisting of a silicon microstrip tracker (SMT) and a central fiber tracker (CFT), both located within a 2 Tesla superconducting solenoidal magnet. Central and forward preshower detectors are located just outside of the superconducting coil. A liquid-argon/uranium calorimeter

has a central section (CC) covering pseudorapidities $|\eta|$ up to ≈ 1, and two end calorimeters (EC) extending coverage to $|\eta| \approx 4$, all three housed in separate cryostats. A muon system resides beyond the calorimetry, and consists of a layer of tracking detectors and scintillation trigger counters before 1.8 Tesla toroids, followed by two more similar layers after the toroids. Luminosity is measured using plastic scintillator arrays located in front of the EC cryostats. The three-tiered trigger and data acquisition systems are designed to accommodate the high luminosities of Run II.

Although a full description of the DØ detector is given in this chapter, the elements that are most relevant for the analysis presented in this dissertation are the calorimeter (Chapter 3.3.4) and tracking system (Chapter 3.3.2).

3.3.1 Coordinate Systems

The coordinate system used for the DØ detector is right-handed. It has the positive z-axis aligned with the direction in which the protons travel and the positive y-axis pointing upwards.

In most cases cylindrical coordinates are used (z, Φ, θ). Φ is the azimuthal angle in the plane perpendicular to the beam (z-axis), where $\Phi=0$ coincides with the positive x-axis. θ is the polar angle relative to the positive z-axis.

Since the colliding protons and antiprotons can exhibit a significant net boost along the z-axis it is suitable to choose a polar angle quantity that is invariant under relativistic transformations. Therefore it is often more convenient to use pseudorapidity η instead of the polar angle θ:

$$\eta = -ln \cdot \left[tan\frac{\theta}{2} \right] \tag{3.2}$$
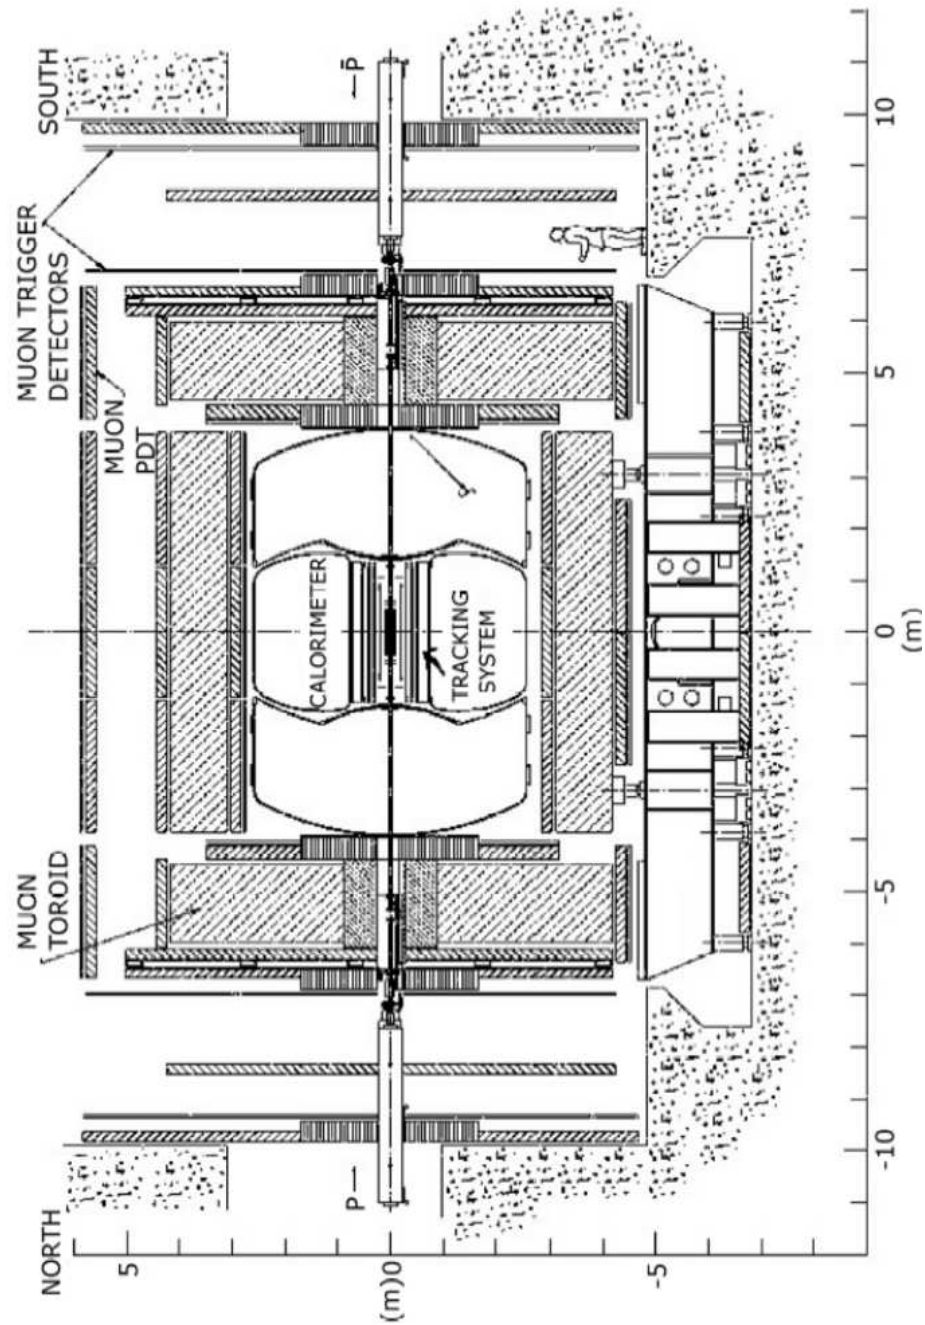

Figure 13. Schematic view of the DØ detector.

The pseudorapidity approximates the true rapidity,

$$y = \frac{1}{2} \cdot ln \left[\frac{E + p_z}{E - p_z} \right] \tag{3.3}$$

in the limit of $m \ll E$ (where m is the invariant mass $m^2 = E^2 - p^2$). We use the term "forward" to describe regions at large $|\eta|$ (> 1.1).

In many cases some of the products of a proton-antiproton collision escape along the beam pipe, which makes it difficult to measure momentum components along the z-axis accurately. Therefore it is more convenient to use the momentum vector projected onto a plane perpendicular to the beam axis (*transverse momentum*):

$$p_T = p \cdot sin\theta. \tag{3.4}$$

In a similar fashion we define *transverse energy* as

$$E_T = E \cdot sin\theta. \tag{3.5}$$

3.3.2 Central Tracking System

The central tracking system is essential in measuring the position of the primary interaction vertex with high accuracy, which subsequently allows good measurement of lepton p_T, jet E_T and missing transverse energy ($\not{E}_T$). It can also detect the presence of b-quarks through the measurement of displaced vertices.
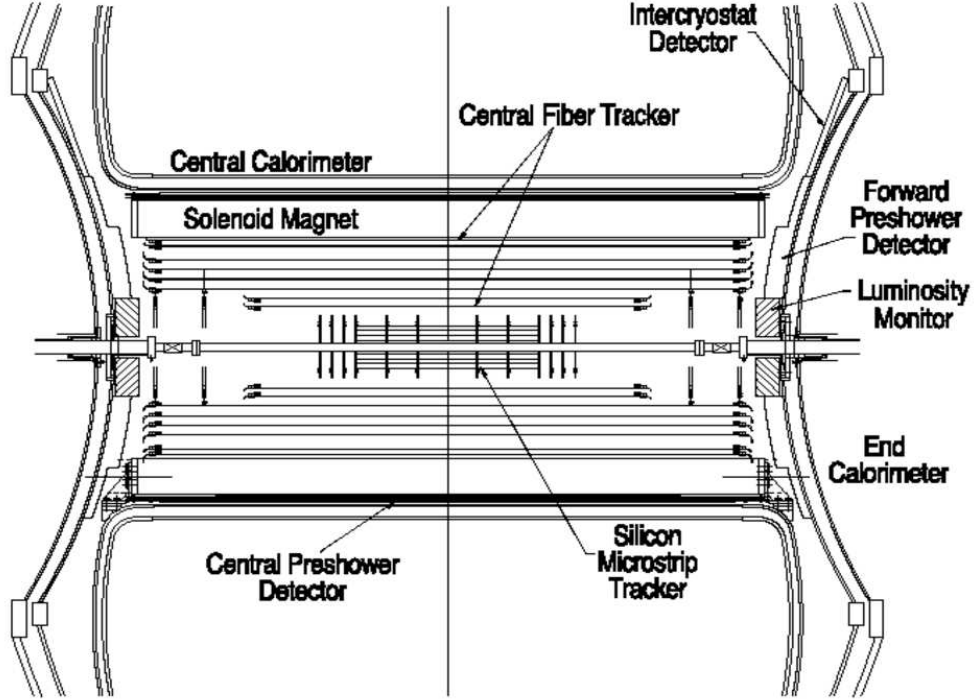

Figure 14. The DØ central tracking system with with solenoid, preshower detectors, luminosity monitor, and calorimeter.

The Central Tracking System consists of the silicon microstrip tracker (SMT), the central fiber tracker (CFT) and the superconducting solenoid (Figure 14, Reference (20)). Combining information from both SMT and CFT, the primary vertex resolution is approximately 35 μm along the beamline. Jets originating from the decay of b-quarks can be measured with an impact parameter resolution of less than 15 μm in $r - \Phi$.

3.3.2.1 Silicon Microstrip Tracker

In order to be able to detect the paths of charged particles emerging from a proton-antiproton collision, the SMT (21) uses wafers of silicon with a thickness of 300 μm. When a charged particle passes through a positive-negative $(p - n)$ junction in silicon it produces electron-hole pairs that can be separated by an applied voltage. The charge which is collected can then be stored in capacitors and later read-out and digitized. The SMT contains of approximately 800,000 individual silicon detectors. Figure 15 shows the design of a basic silicon detector unit (*ladder*) (20).

The SMT is designed in such a way that tracks of charged particles are perpendicular to detector material over a large range of η values. The structure of the device is mostly dictated by the fact that the interaction region is spread out with respect to the center of the detector ($\sigma \approx 25$ cm). This leads to a design of barrel modules combined with disks in the center and larger disks in the forward region (Figure 16, Reference (20)). The SMT has six barrels along the z-axis, each containing four detector layers with a maximal outer radius of 10.5 cm. There are twelve small diameter double-sided "F" disks and four large diameter single-sided "H" disks to cover the far forward region ($|\eta| <$3). The F-disks are at $|z| = 12.5, 38.2, 43.1$ and 53.1 cm. The centers of the H-disks are located at $|z| = 100.4, 121.0$ cm.

3.3.2.2 Central Fiber Tracker

The Central Fiber Tracker (CFT) (22) is located in between the SMT and the solenoid magnet. The purpose of the CFT is to improve the detection of charged particle tracks within $|\eta| < 2$. It consists of approximately 70,000 scintillating fibers mounted on eight concentric
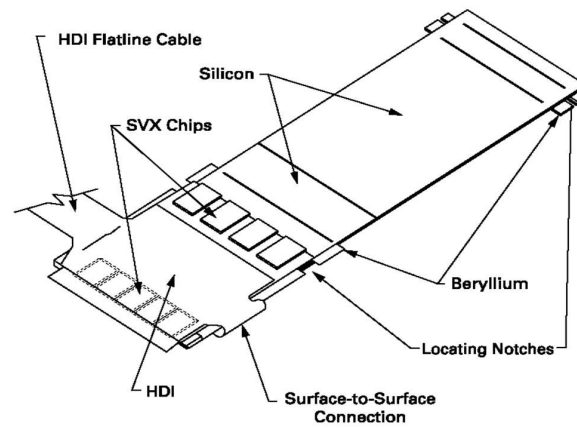

Figure 15. Double-sided ladder design, n-side.
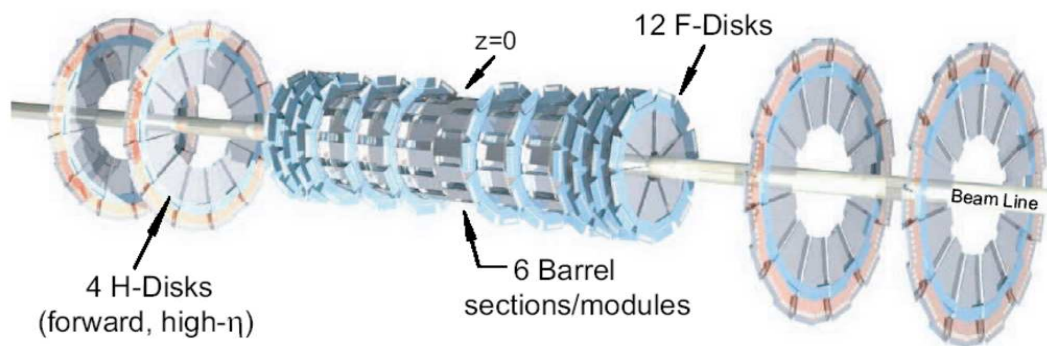

Figure 16. SMT disk and barrel design.

support cylinders with inner and outer radii of 20 and 52 cm, respectively. Each cylinder carries two layers of fibers running parallel to the beampipe (*axial layers*), and two layers of fibers oriented at small angles of $\pm 3°$ (*stereo layers*) (Figure 17, Reference (23)). The scintillating fibers have a diameter of 835 μm and are composed of a scintillating core surrounded by a layer with a high index of refraction, which leads to total internal refraction.

Charged particles passing through a scintillating fiber excite the molecules in the fiber which subsequently release photons in the yellow-green part of the visible light spectrum as they relax to their ground states. Clear fiber waveguides carry the scintillation light to visible light photon counters (VLPCs) that convert the light into electrical signals. The VLPCs are silicon avalanche photodetectors that operate at liquid helium temperature in order to reduce the background due to electronic noise.

3.3.2.3   Solenoidal Magnet

The superconducting solenoidal magnet significantly improves the capabilities of the DØ detector with regard to the detection of charged particle tracks and momentum resolution. The location and physical size of the magnet are constrained by the available space between the inner tracking system and the vacuum vessel of the central calorimeter. The magnet has a length of 2.73 m and a diameter of 1.42 m and provides uniform field of 2 T (20 kG) over most of the region covered by the inner tracking system (Figure 18, Reference (20)). Figure 19 shows a perspective view of the solenoid inside the central calorimeter with its chimney and control dewar (20).
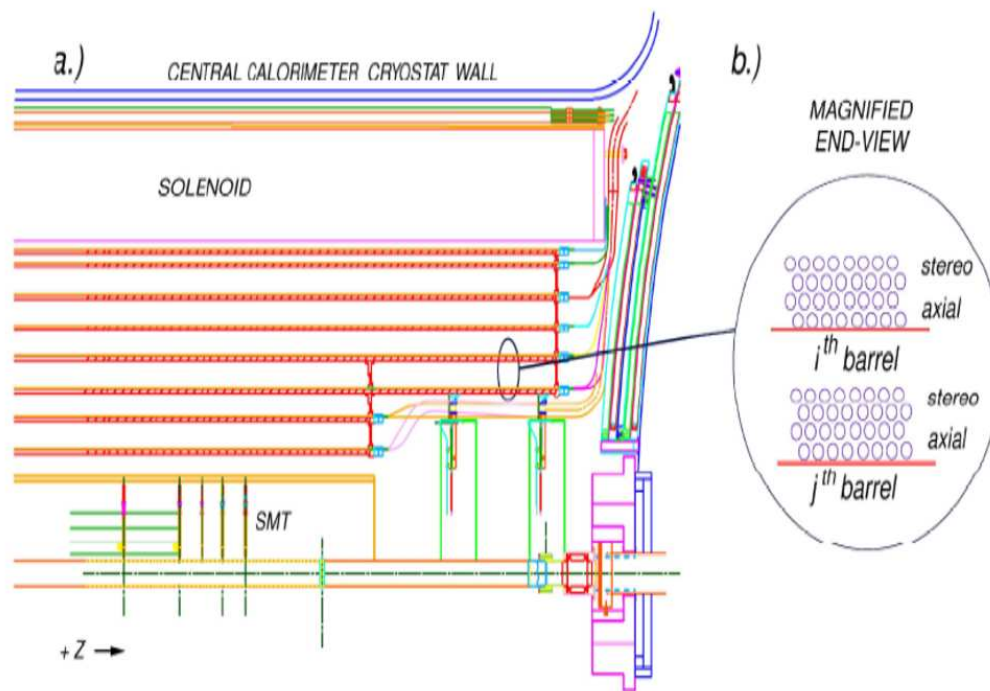

Figure 17. a) Location of the Central Fiber Tracker (CFT). b) Closeup view of axial and stereo layers.
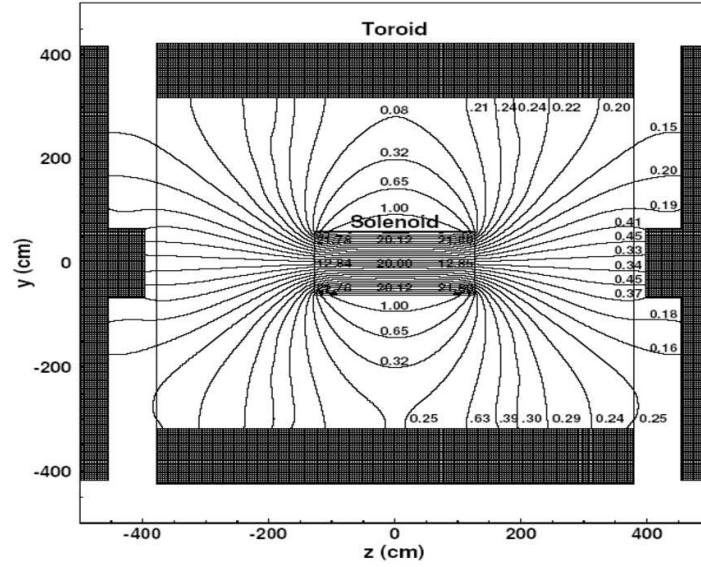

Figure 18. $y - z$ view of the DØ magnetic field with both the toroid and solenoid magnets at full current. Numbers are in kG (10 kG = 1 T).

3.3.3 Preshower Detectors

The preshower detectors (24; 25) are designed to improve the identification of electrons and background rejection. By the time a charged particle has reached the preshower detectors it has already passed through several detectors as well as other upstream material like cables and support structures. The preshower detectors allow to correct for upstream energy losses in the offline event reconstruction. Due to their fast response time the preshower detectors can also be used for Level 1 triggering (see Chapter 3.4.1).

Scintillators are used to detect both position and energy of charged particles. In contrast
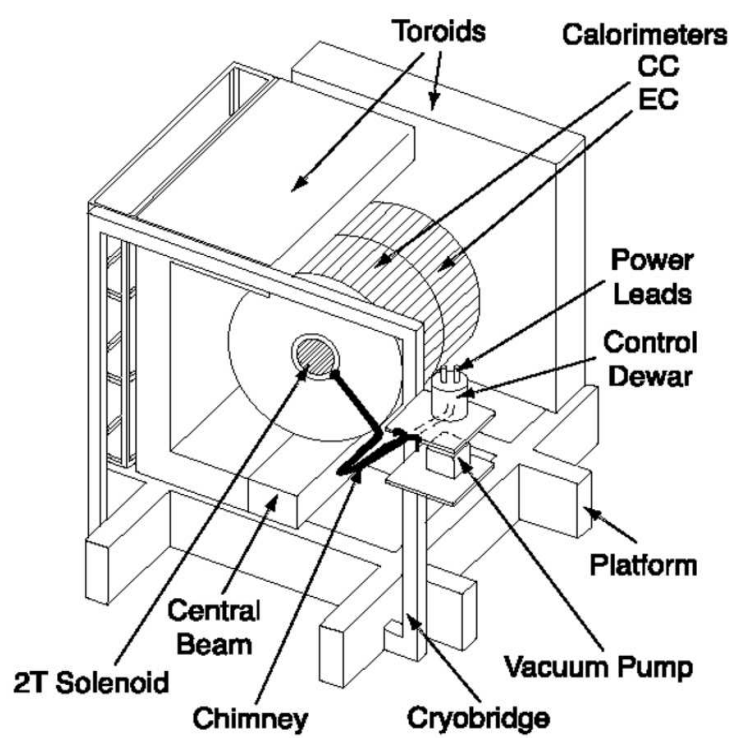

Figure 19. Perspective view of the solenoid inside the central calorimeter.
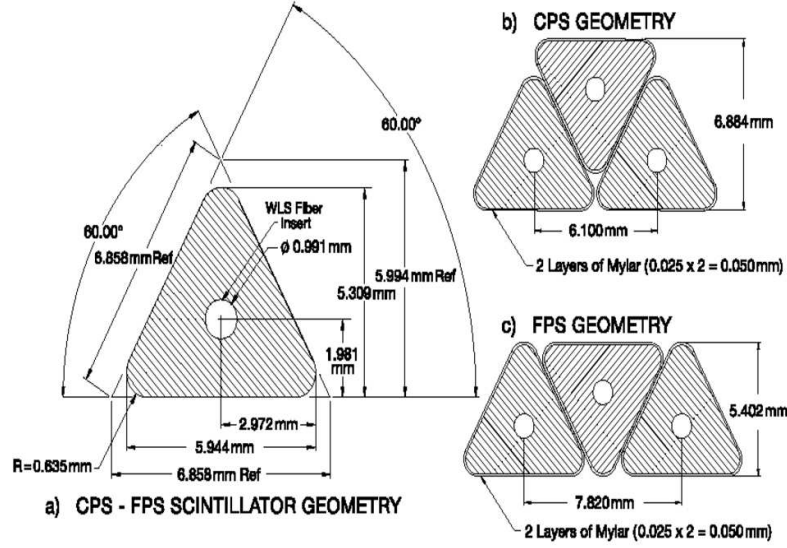

Figure 20. Cross section and layout geometry of the CPS and FPS scintillator strips.

to the scintillators used in the CFT, preshower scintillators are triangular shaped (Figure 20, Reference (20)). This allows to arrange layers of scintillators without creating any dead space and thereby improving the accuracy of position measurements. The center of each scintillator carries a wavelength-shifting fiber which collects the light created by passing charged particles. The light is transmitted via clear fibers to VLPCs for readout.

3.3.3.1   Central Preshower Detector

The Central Preshower Detector (CPS) is located in the 5 cm gap between the solenoid and the central calorimeter, covering the region $|\eta| < 1.3$ (Figure 14, Reference (20)). It consists of a layer of lead radiator which has a thickness corresponding to approximately one radiation-

length (X_0), followed by three layers of triangular scintillator strips. The purpose of the lead radiator is to ensure that the total amount of material encountered by a passing particle is constant at all pseudorapidities. The scintillating layers are arranged in an axial-u-v geometry, with a u stereo angle of $23.8°$ and a v stereo angle of $24.0°$. Each layer has a total number of 2,560 readout channels.

3.3.3.2   Forward Preshower Detector

The two Forward Preshower Detectors (FPS) are attached to the faces of the end calorimeters and cover a region of $1.5 < |\eta| < 2.5$ (Figure 14, Reference (20)). Each detector consists of an upstream double layer of scintillator strips (minimum ionizing particle layers, or MIP layers), followed by a lead-stainless-steel absorber layer, and another double layer of scintillator strips behind it (shower layers). This configuration allows for the distinction between electron-like and photon-like objects. While an electron-like object will create a minimum ionizing energy deposit in the MIP layers, a photon-like object will not. Therefore electrons can be identified by requiring spatially matched energy deposits in both the MIP layers and the shower layers, whereas photons will only have energy deposits in the shower layers.

3.3.4   Calorimeter

The main purpose of the calorimeter system (26) is to measure the energy deposits from electrons, photons, and jets. It also allows direct identification of electrons, photons, jets, and muons. In addition, measurements of the transverse energy balance in an event can detect the presence of neutrinos.

The calorimeter system consists of a central calorimeter (CC) covering $|\eta| < 1.2$ and two end

calorimeters (EC), covering $1.3 < |\eta| < 4.0$ (Figure 21, Reference (20)). Each of the calorimeters has an electromagnetic section, followed by fine and coarse hadronic sections. Since liquid argon is used as the active medium, all calorimeters are contained within cryostats. Different types of materials are used for absorber plates:

- 3 mm (4 mm) plates of depleted uranium for the CC (EC) electromagnetic sections.

- 6 mm plates of uranium-nobium (2%) for the fine hadronic sections.

- 46.5 mm plates of copper (stainless steel) for the CC (EC) coarse hadronic sections.

A typical calorimeter cell is shown in (Figure 22, Reference (?)). Each cell consists of a grounded absorber plate and a signal board maintained at a positive high voltage of typically 2 kV. The 2.3 mm gap between the absorber plate and signal board is filled with liquid argon. The calorimeter cells are arranged to form pseudo-projective towers (Figure 23, Reference (20)).

In order to measure the energy of electromagnetically interacting objects, the calorimeter takes advantage of the electromagnetic shower process. For example, an incoming electron will emit Bremsstrahlung photons when passing through the dense absorber material and will interact with the nuclei in the absorber via Coulomb interaction. The emitted photons will subsequently decay into electron-positron pairs. This chain of processes continues untill the energies of the secondary particles fall below the threshold for pair production. After that the particles mainly interact via ionization. At each stage of the electromagnetic shower, charged particles are ionizing the liquid argon. The high voltage between the absorber plates and signal boards is then used to collect the ionization charges, which allows a measurement of the energy in the shower. Typical transverse sizes of electromagnetic showers are in the range of 1-2 cm.

Hadronic showers are induced by the interaction between hadronic particles and the nuclei of the absorber material via the strong nuclear force. Secondary hadronic particles then further interact via inelastic nucleus collisions till their energy falls below a threshold. Typical transverse sizes of hadronic showers are of the order of 10 cm. The space in between the central and end calorimeters ($1.1 < |\eta| < 1.4$) is referred to as the intercryostat region (ICR). In order to be able to measure the energies of particles that pass through this gap in the calorimeter coverage, additional detectors are used. Calorimeter cells called massless gaps (MG) are installed before the first layer of uranium inside of the central and end cryostats. Additionally, a ring of scintillator tiles mounted to the exterior surface of the end cryostats comprises the intercryostat detector (ICD).

Figure 24 shows the different calorimeter detection layers for a given η value (27).

3.3.5 <u>Muon System</u>

Due to their large mass and long lifetime, muons pass through the calorimeter by depositing only a small amount of energy (≈ 2.5 GeV) via ionization. Therefore, the outermost subdetector is dedicated to the detection of muons (Figure 25, Reference (**?**)). The muon system is separated into central and forward detectors. A 1.9 T iron toroid magnet is used for muon momentum measurements.

Proportional Drift Tubes (PDT), Mini Drift Tubes (MDT), and scintillators are the main detection elements used in the muon system. Drift tubes collect the ionization charges created by muons passing through a gas mixture onto high voltage wires. Correlating the arrival times of
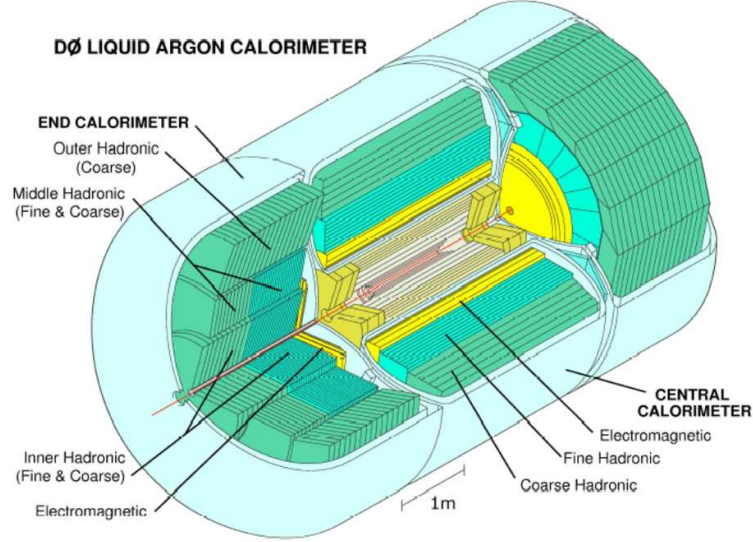

Figure 21. Isometric view of the central and two end calorimeters.

ionization charges from different drift tubes with the beam crossing time, allows to extrapolate the path of muons as they pass through the detector. Scintillators are mainly used for their good timing resolution ($\approx$ 4 ns) which allows a way to trigger on muons.

The central muon system (28) covers the region of $|\eta| < 1.0$ and is referred to as the Wide Angle Muon System (WAMUS). It consists of three PDT layers, with the first layer (A layer) in between the toroid magnet and the calorimeter, and two more layers (B and C layers) after the toroid magnet. Additional layers of scintillators before the A layer and covering the outside of the muon system allow for spatial and precise timing measurements to reject cosmic rays.

The forward muon system (29) covers the region of $1.0 < |\eta| < 2.0$ and is referred to as the
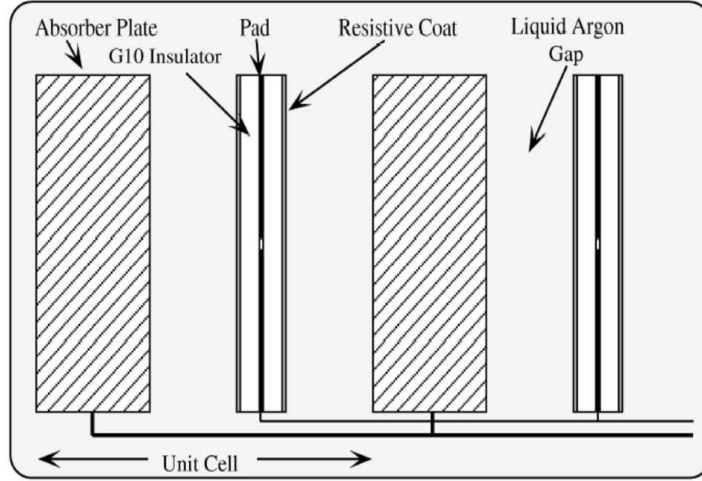

Figure 22. Schematic view of two calorimeter cells.

Forward Angle Muon System (FAMUS). It consists of three MDT layers and scintillators, with the first layer (A layer) before the toroid magnet, and two more layers (B and C layers) after the toroid magnet.

3.4   The DØ Trigger and Data Acquisition Systems

DØ uses a three level trigger system (23; 30) to handle the high proton-antiproton collision rate of 2.5 MHz. Each succeeding level of triggering processes fewer events, with more sophisticated trigger algorithms. At the first stage the Level 1 (L1) system uses a hardware trigger to reduce the event rate to ≈ 2 kHz. At the next stage the Level 2 (L2) system further reduces the event rate to ≈ 1 kHz. L2 uses hardware engines associated with specific detector subsystems and a single global processor for the final L2 trigger decision. In the last step the Level 3 (L3)
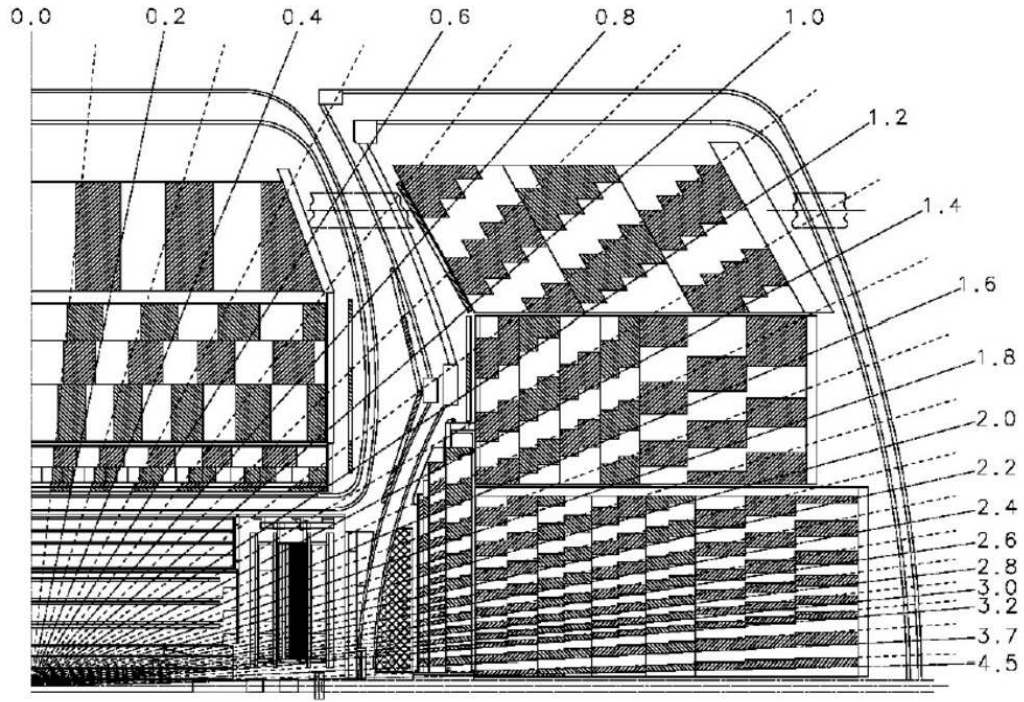

Figure 23. Schematic view showing the calorimeter segmentation pattern. The shading pattern indicates cells for signal readout. The radial lines show the detector pseudo-rapidity intervals.
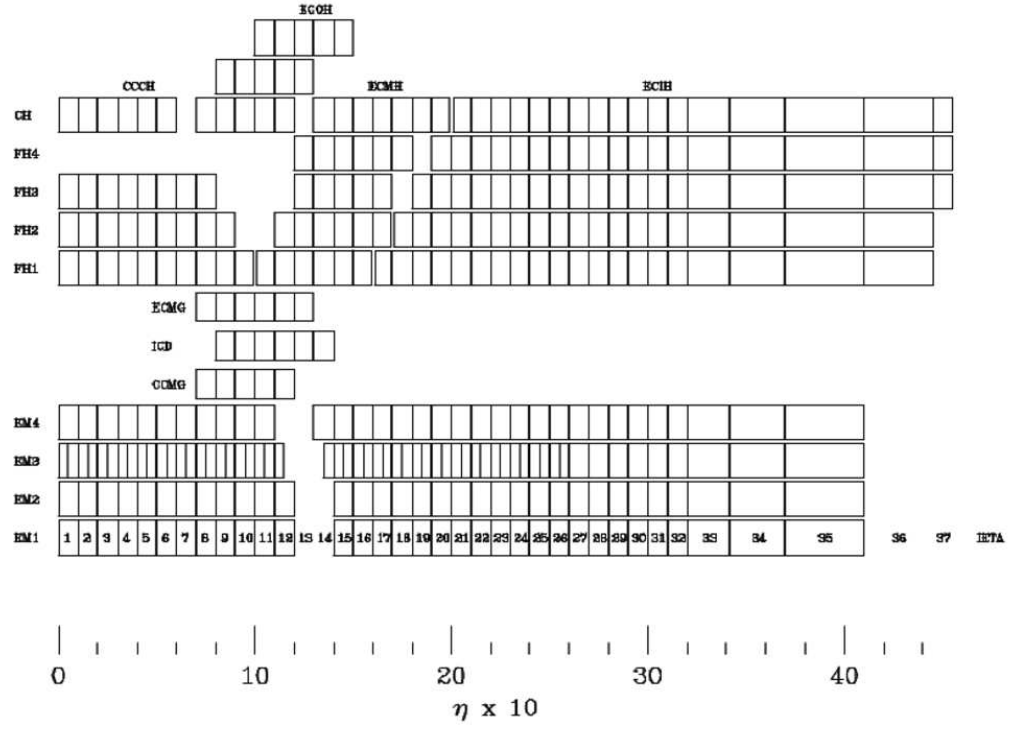

Figure 24. Schematic view of different calorimeter detection layers vs η.
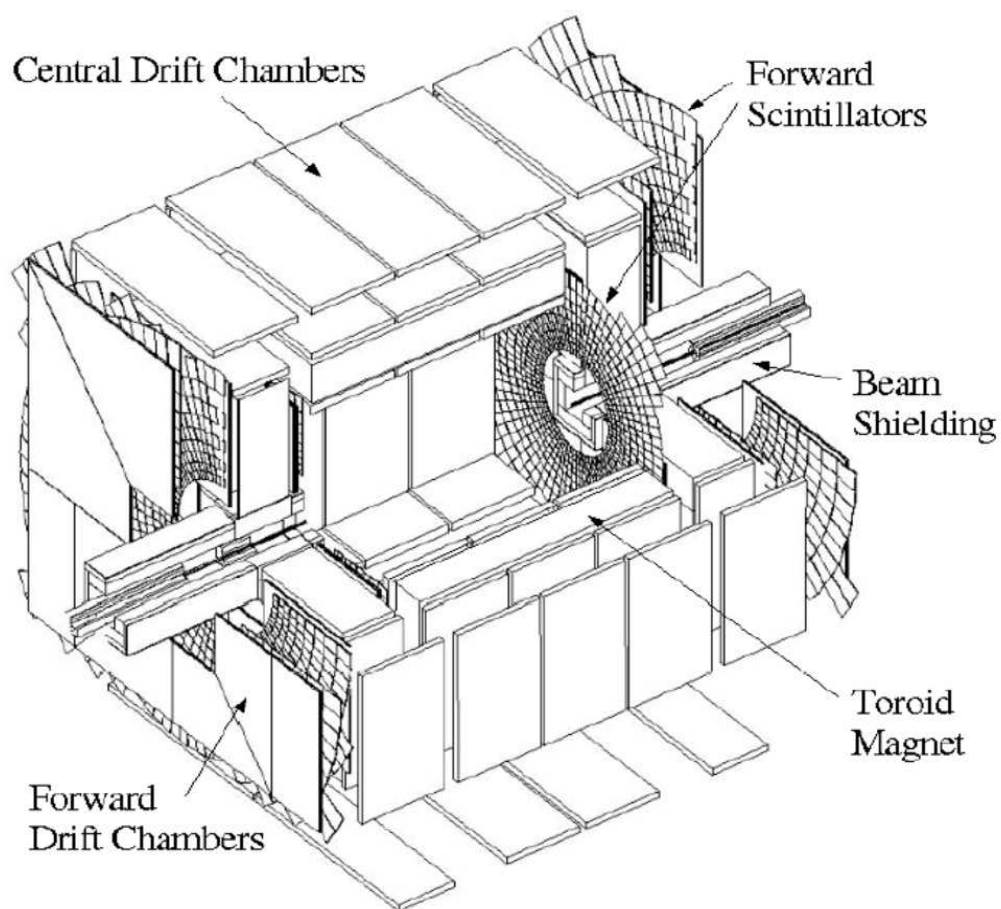

Figure 25. The DØ muon system.

system which consists of a farm of microprocessors reduces the event rate to $\approx$ 50 Hz. Only those events that pass all three trigger levels are stored for further offline reconstruction and analysis.

3.4.1   The Level 1 Trigger

The L1 trigger system uses information from the tracking, preshower, calorimeter and muon subdetectors to provide an event rate reduction by a factor of $\approx$ 1000. Field programmable gate arrays (FPGAs) check whether a given event satisfies one of up to 128 L1 trigger conditions. If at least one trigger condition is satisfied the event information is digitized and buffered to await a L2 decision. L1 trigger decisions are made within a 4.2 μs time window.

3.4.1.1   The Level 1 Calorimeter Trigger

For trigger purposes the calorimeter is segmented into 1280 trigger towers of $\Delta\eta \times \Delta\Phi = 0.2 \times 0.2$. Level 1 calorimeter (L1CAL) trigger decisions are based on the amount of transverse energy deposited in the electromagnetic layers (EM) and electromagnetic plus fine hadronic layers (TOT) of the trigger towers. L1CAL trigger conditions require that a specific number of EM or TOT trigger towers be above a certain transverse energy threshold. In addition L1CAL can also impose thresholds on the total sum of transverse energy and the missing transverse energy in a given event.

3.4.1.2   The Level 1 Central Track Trigger

The Level 1 Central Track Trigger (L1CTT) uses information from the CFT and CPS subdetectors in the central region ($|\eta|$ <1.7), and information from the CFT and FPS subdetectors in the forward region (1.4< $|\eta|$ <2.5). Possible track candidates are identified by FPGAs using
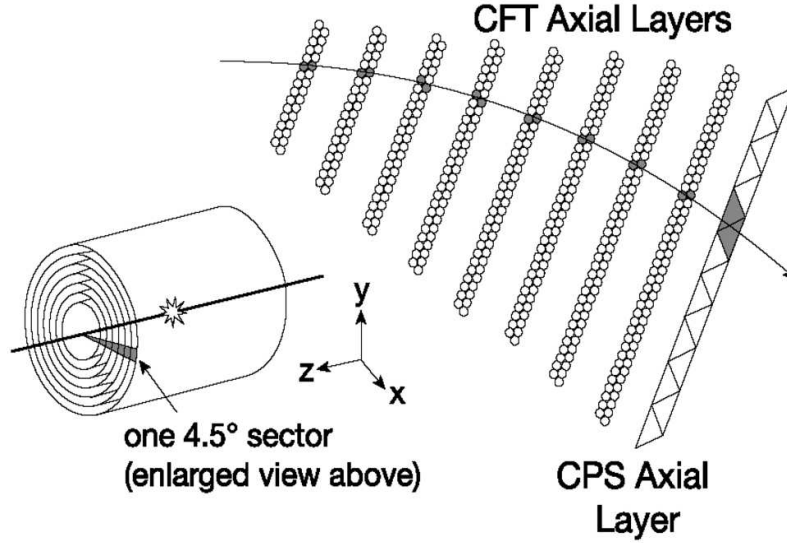

Figure 26. A hypothetical L1CTT track with hits in eight CFT axial doublet layers and the CPS axial layer.

hit patterns in the axial layers of the CFT and matching energy deposits in the preshower detectors (Figure 26, Reference (20)). The p_T of a track candidate can be estimated by the azimuthal bend of the CFT hits. L1CTT trigger conditions require that a track candidate be above a certain p_T threshold with the possibility of a matching hit in the corresponding preshower subdetector.

3.4.1.3   The Level 1 Muon Trigger

The Level 1 Muon Trigger (L1Muon) uses information from the muon wire chambers, muon scintillators, and L1CTT tracks. L1Muon trigger logic is implemented in FPGAs and trigger

conditions require a combination of criteria based on p_T thresholds, geographical region, track quality and multiplicity.

3.4.2 The Level 2 Trigger

The L2 trigger system was designed to reduce the event rate by a factor of 10. It receives inputs from both the L1 system and the detector subsystems. L2 operates in two stages. In the first stage, subdetector-specific preprocessors form physics objects such as EM energy clusters or tracks. Individual preprocessors for the tracking, preshower, calorimeter and muon subdetectors run in parallel and are located in separate crates. L2 preprocessor physics objects are then used at the second stage by a global processor. The L2 global processor makes the final L2 trigger decision by imposing selection criteria on the preprocessor physics object, including correlations between multiple detector subsystems.

The two-stage L2 architecture (*stochastic pipeline*) can make trigger decisions within a 100 μs time window (see Appendix B for a detailed description of the L2 trigger system). Events passing L2 trigger requirements are flagged for full detector readout and further refined analysis at the L3 triggering stage.

3.4.2.1 The Level 2 Calorimeter Preprocessor

The Level 2 calorimeter preprocessor (L2Cal) receives the full list of 2560 EM and TOT trigger towers from L1CAL.

The L2 jet algorithm forms jet objects by clustering 5×5 groups of TOT trigger towers centered around seed towers. A jet seed tower is any TOT trigger tower with $E_T \geq 2$ GeV. The list of seed towers for the L2 jet algorithm is E_T-ordered. Depending on the configuration,

overlapping L2 jet candidates can be reported as separate jets or simply the highest-E_T jet. An E_T-ordered list of all L2 jets is sent to the L2 global processor.

The L2 Electron/photon algorithm forms EM objects by adding the transverse energies of EM seed towers with their largest E_T neighbors. An EM seed tower is any EM trigger tower with $E_T \geq 1$ GeV. The list of seed towers for the L2 EM algorithm is E_T-ordered. The L2 EM algorithm can be configured in such a way that only the seeds (without considering the neighboring towers) are used to form EM objects. To reduce background the EM energy fractions for both the leading and next-to-leading EM cluster that form the EM object are calculated. Additionally, the isolation of the EM cluster from other energy deposits in the calorimeter is evaluated. An E_T-ordered list of all L2 EM objects and parameters is sent to the L2 global processor.

3.4.2.2   The Level 2 Muon Preprocessors

The Level 2 Muon system (L2Muon) consists of two components: a preprocessor for the central muon region (L2 Muon Central, or L2MUC) and a preprocessor for the forward muon region (L2 Muon Forward, or L2MUF). L2Muon receives inputs from Level 1 (L1Muon), and the muon subdetector drift chambers and scintillators. This allows to improve muon triggering capabilities by incorporating better calibration and timing information from the muon scintillators. Muon tracks at L2 contain η and ϕ information, as well as p_T, sign, and timing information.

3.4.2.3 The Level 2 Preshower Preprocessor

The Level 2 preshower preprocessor (L2PS) receives inputs from the L1 trigger system. Based on preshower detector information it forms clusters with η and ϕ coordinates that can then be matched with calorimeter trigger towers or CFT trigger tracks at the L2 global processing stage.

3.4.2.4 The Level 2 Tracking Preprocessor

The Level 2 tracking preprocessor uses information from L1CTT and the SMT to form lists of L2 track candidates that can be used by the L2 global processor for triggering. This part of the L2 trigger system is still under development. It would allow to trigger on vertices that are displaced from the primary interaction vertex. Displaced vertices are characteristic of long-lived particles such as B-Mesons, and can therefore be used to identify heavy-flavored quarks.

The L2 tracking preprocessor can be operated in two different modes. In the first mode of operation (L2 Central Track Trigger, or L2CTT) it further refines tracking information coming from L1CTT. In the second mode of operation (L2 Silicon Track Trigger, or L2STT) it combines L1CTT and SMT information. Figure 27 shows the conceptual design of L2STT (20). It uses hit information from the first and last layer of the CFT to define a *road*, and then extrapolates that road into the SMT to find additional hits in the axial strips of the SMT silicon ladders.

3.4.2.5 The Level 2 Global Processor

The Level 2 global processor (L2GBL) receives lists of trigger objects that are generated by the L2 preprocessors (L2Cal, L2MUC, L2MUF, L2PS, L2CTT, L2STT). It creates global trigger
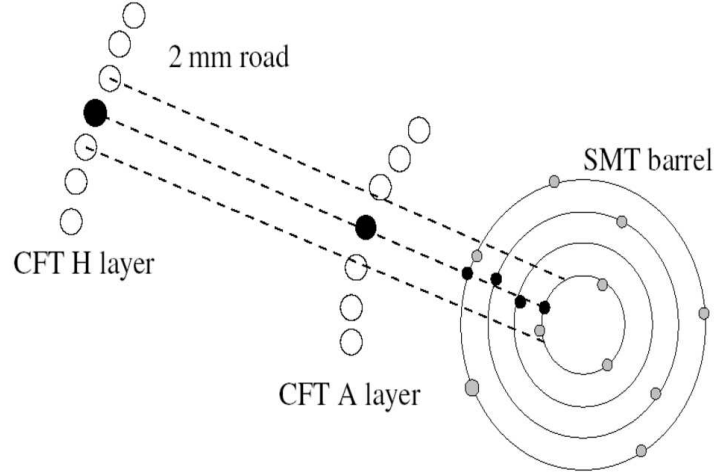

Figure 27. The definition of roads based on L1 tracks and SMT hit selection in L2STT.

objects by either using the trigger objects generated by the preprocessors or by combining trigger object information from different preprocessors. For example, spacial correlations between track candidates and EM energy deposits in the calorimeter can be used to select electron candidates. L2GBL makes the final L2 trigger decision by imposing cuts on global trigger objects that are defined by trigger list information which is parsed from the trigger control computer.

3.4.3   The Level 3 Trigger and Data Acquisition

The L1 and L2 trigger systems do not use the full detector readout for their trigger decisions. The event rate needs to be reduced to 1 kHz or below, so that the Level 3 (L3) trigger system can take advantage of the full detector readout. L3 then further reduces the event rate to $\approx$ 50 Hz. The average event size is $\approx$ 200 kByte.

The L3 trigger system is based on software algorithms that resemble the algorithms for offline event reconstruction (see Chapter 4) as closely as possible, given restrictions due to available processing power.

The data acquisition system (L3DAQ) is based on a single Cisco 6509 Ethernet switch that allows data transfer rates of 250 Mbyte/s. Figure 28 illustrates the main hardware components of the data acquisition system (20). Detector data is transfered from commodity VME single-board computers (SBCs), via the Ethernet switch to the individual L3 farm nodes. A supervisor process running on a separate CPU provides the interface between the main DØ run control system (COOR) and L3DAQ.

After passing L3 trigger requirements the data are buffered to local disks and finally transferred to a permanent storage facility.
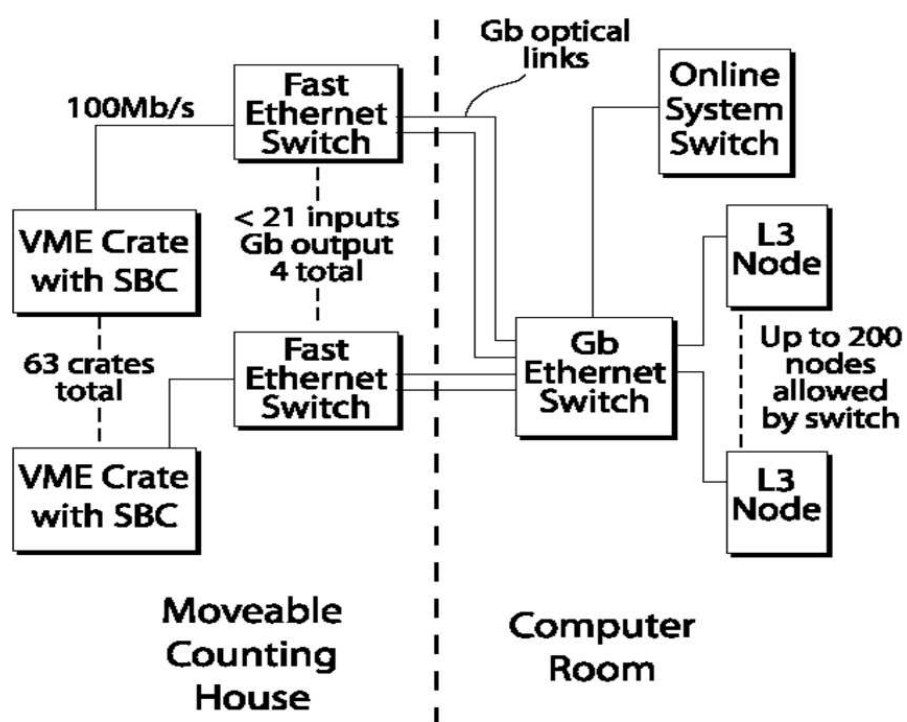

Figure 28. Main L3DAQ hardware components.

CHAPTER 4

OFFLINE EVENT RECONSTRUCTION

This chapter describes how physical objects like electrons or jets, are formed or *reconstructed* from the raw detector data. A collection of complex software algorithms written in C++ called *d0reco* (31) is used for this reconstruction process. As described in the previous chapter, a stream of digital readout signals from the subdetectors is recorded for each event that passes all three levels of triggering. Powerful PC computing farms are deployed to analyze the data and reconstruct candidates of physical objects (electrons, jets, tracks, etc) that can then be used in the final analysis.

4.1 Track Reconstruction

In order to reconstruct track candidates, two different types of algorithms are used. The *Alternative Algorithm* (AA) (32) uses a road-following method, while the *Histogramming Track Finder* (HTF) (33) relies on a histogramming method.

The AA method starts from any combination of three hits in the SMT barrels or disks. Moving outwards, towards the CFT, it then extrapolates the sequence of hits to the next SMT or CFT layer. If a hit is found within a configurable expectation window, a χ^2 test is performed. If the χ^2 value is below a certain threshold, the newly found hit is associated with the track candidate. If no hit is found, it is recorded as a *miss*. Construction of track candidates ends when the last layer of the CFT is reached, or when three misses are recorded.

The HTF method takes advantage of the fact that the trajectory of a charged particle moving perpendicular to a homogeneous magnetic field can be characterized by the three parameters ρ, d_0, Φ, where $\rho = qB/p_T$ is the radius of curvature, d_0 is the distance of closest approach with respect to (0,0) (*impact parameter*), and Φ is the direction of the track at the point of closest approach to (0,0). Examining only track candidates with small impact parameters, every pair of hits in (x,y) coordinate space belonging to the same track corresponds to a single point in parameter space (ρ, Φ). Therefore, after examining every pair of hits and filling a 2-D (ρ, Φ) histogram, a peak in the histogram corresponds to a track candidate.

Both algorithms generate lists of track candidates. A final list of tracks is generated after eliminating duplicates, and applying additional selection criteria (using number of hits, number of misses, and χ^2 values). Figure 29 shows an example of hits and reconstructed tracks (34).

4.2   Primary Vertex Reconstruction

The primary vertex (PV) is the location of the proton-antiproton hard scatter collision. It is important to identify the position of the PV with high accuracy, since it is an essential ingredient to reconstruct jets, electrons and missing transverse energy. It is also important to select an algorithm (35) which distinguishes between the hard scatter vertex and the vertices from additional *minimum bias* (MB) interactions.

Based on the list of reconstructed tracks (see Chapter 4.1), a list of vertices is generated by extrapolating the tracks back to the z-axis. Clusters of vertices are then formed by selecting vertices within 2 cm of each other along the z-axis. In each vertex cluster, the vertex with
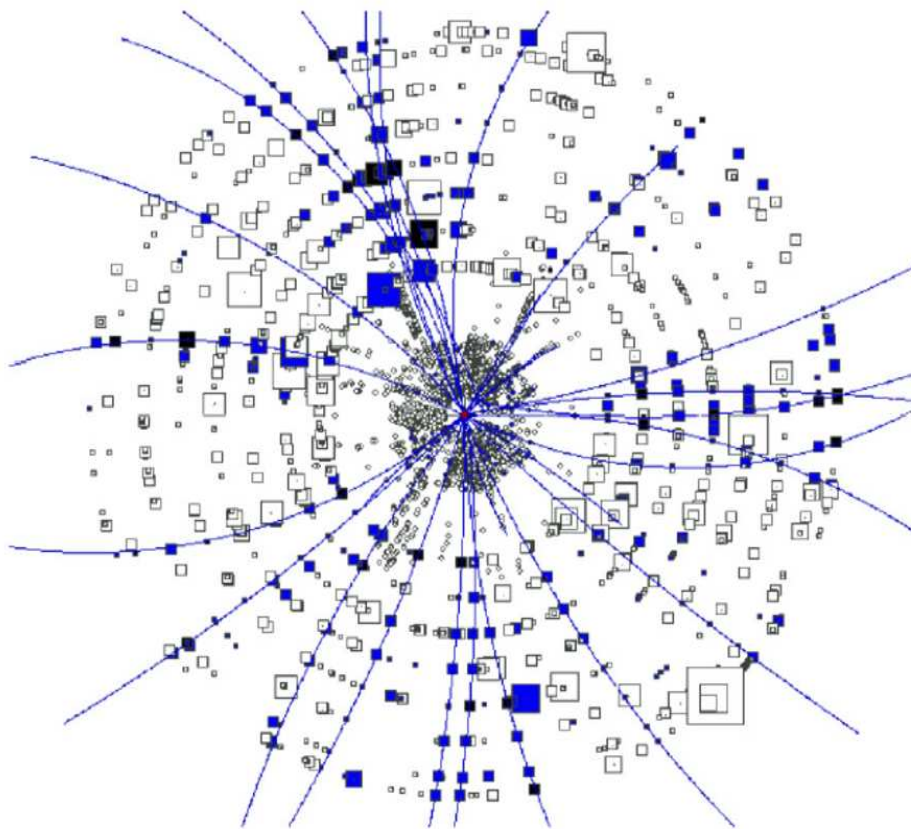

Figure 29. Axial view (looking down the beam-pipe) of a recorded event showing hits and reconstructed tracks. CFT hits are represented by squares, and SMT hits are represented by circles. Hits are colored solid if they are associated with a reconstructed track (solid lines). The curvature of the reconstructed tracks is due to the solenoidal magnetic field, which is pointing out of the page.

the highest number of tracks pointing at it is stored in a list of "selected" vertices. For every selected vertex, nearby tracks are used to compute the probability that the vertex does not come from a MB interaction. The computation of this probability is based on the assumption that tracks coming from MB interactions will have a smaller transverse momentum compared to tracks coming from the hard scatter. Finally, the vertex with the smallest MB probability is chosen as the PV.

4.3   Electromagnetic Object Reconstruction and Identification

Electromagnetic objects (EM objects), such as electrons and photons, are initially identified based on calorimeter information. Since photons do not leave signals in the tracking system, a track matched to the energy deposit in the calorimeter distinguishes electrons from photons.

EM object reconstruction begins with forming initial calorimeter clusters. Different algorithms can be used to find those initial clusters:

- Simple-Cone tower clustering algorithm ("Scone Method")

- Cell Nearest Neighbor clustering algorithm ("CellNN Method")

- Track extrapolation clustering algorithm ("Road Method")

In this analysis, objects reconstructed with the simple cone algorithm are used.

4.3.1   Simple-Cone Clustering Algorithm

The simple-cone algorithm (36) clusters calorimeter cells of size $\Delta\eta \times \Delta\Phi = 0.1 \times 0.1$. Each cell is required to have at least 1.5 GeV of transverse energy. Additionally, for each cell the
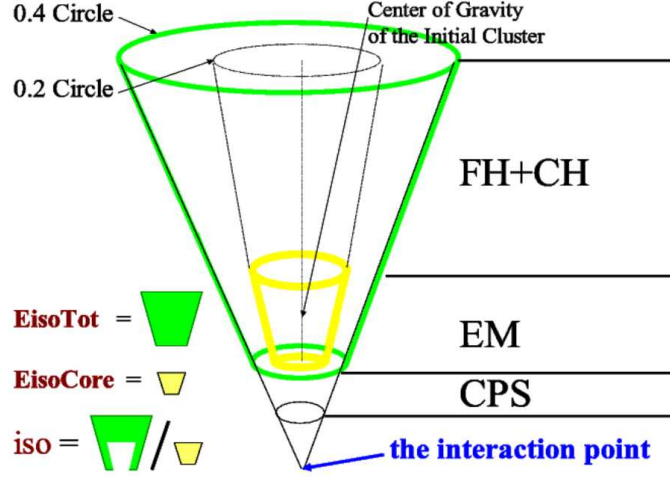

Figure 30. Illustration of the Isolation Parameter: *EisoTot* is the total energy in a cone of radius 0.4, and *EisoCore* is the energy in the EM layers in a cone of radius 0.2.

ratio of the energy in the EM layers to the total energy (EM fraction) is required to be above 0.9. Next, all clusters satisfying the above criteria are tested for *isolation*:

$$isolation = \frac{EisoTot - EisoCore}{EisoCore} \tag{4.1}$$

Figure 30 illustrates the definition of the isolation parameter (36). All initial EM clusters are required to have an isolation of less than 0.2. The isolation parameter gives a measure of how deep and narrow a given cluster is. EM objects tend to deposit most of their energy in a narrow region of the EM layers, while hadrons deposit their energies in the hadronic layers in a much wider radius.

4.3.2   Electromagnetic Object Identification Parameters

A set of various parameters is calculated for every EM cluster that passes the initial quality criteria. This allows flexibility when defining EM objects at the analysis stage.

ID: All EM clusters that pass the initial quality criteria are assigned an ID of 10. If in addition a cluster has a track loosely matched (in η and Φ) to it, it is assigned an ID of ± 11 ("+" for electrons, "−" for positrons).

Isolation: See Chapter 4.3.1.

Electromagnetic Fraction: The electromagnetic fraction (EM fraction) is another discriminant between EM and hadronic calorimeter energy deposits. It takes advantage of the fact that EM showers are almost entirely contained within the EM layers of the calorimeters. Figure 31 illustrates the definition of the EM fraction parameter (36).

H-Matrix: The H-Matrix technique allows a distinction between EM and hadronic energy deposits, by analyzing the longitudinal and transverse shape of the showers. Based on MC generated electrons a covariance matrix (M) is defined using a set of seven discriminant variables :

$$M_{ij} = \frac{1}{N} \sum_{n=1}^{N} \left(x_i^n - \langle\, x_i\, \rangle \right) \left(x_j^n - \langle\, x_j\, \rangle \right) \tag{4.2}$$

where x_i^n is the value of variable i for electron n, and $\langle\, x_i\, \rangle$ is the mean value of variable i. The seven variables that are used are listed below:

- Shower energy fraction in 1st, 2nd, 3rd, and 4th EM layer of the calorimeter.

- Cluster size in $r - \Phi$ based on the 3rd EM layer of the calorimeter.
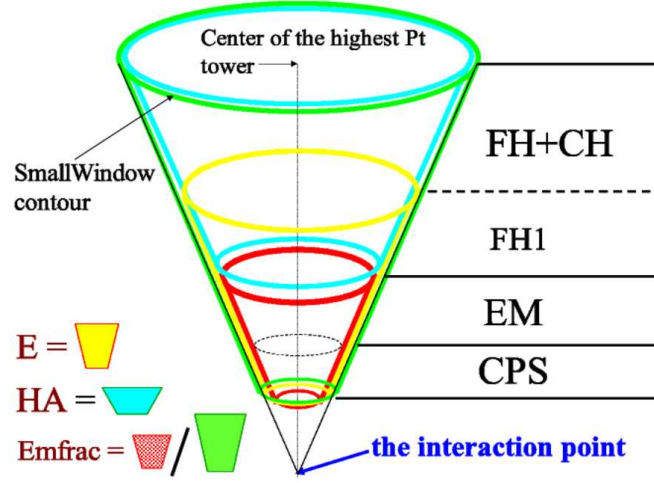

Figure 31. Illustration of the EM fraction parameter: EM fraction is the ratio between the energy in the CPS plus EM layers, and the energy in the CPS plus EM layers plus hadronic layers.

- Total shower energy.

- Primary vertex position.

The H matrix is defined as the inverse of the covariance matrix (Equation 4.2):

$$H \equiv M^{-1} \tag{4.3}$$

Using the H matrix one can calculate a χ^2-like variable that gives a measure of the likelihood that a given shower k is consistent with an EM object shower:

$$\chi^2 = \sum_{ij} (x_i^k - \langle\, x_i\, \rangle)\, H_{ij}\, (x_j^k - \langle\, x_j\, \rangle) \tag{4.4}$$

Track Matching: Requiring that a track is associated with a calorimeter EM cluster is a powerful discriminant between electrons and photons. In this analysis *global tracks* are used for tracking confirmation, i.e. tracks based on information from both the CFT and SMT subdetectors. Using calorimeter and tracking information the following χ^2 variable is calculated:

$$\chi^2 = \left(\frac{\Delta\Phi}{\sigma_\Phi}\right)^2 + \left(\frac{\Delta z}{\sigma_z}\right)^2 + \left(\frac{E_T/p_T - 1}{\sigma_{E/p}}\right)^2 \tag{4.5}$$

where in Equation 4.5:

- $\Delta\Phi$ (Δz) is the difference in Φ (z) between the EM cluster position in the 3rd EM calorimeter layer and the extrapolation of the track to the same layer.

- σ_Φ, σ_z, and $\sigma_{E/p}$ are the root-mean-squares of the experimental measurements of each quantity.

- E_T/p_T is the ratio of the transverse energy of the EM calorimeter cluster and the transverse momentum of the track.

A track is matched to an EM cluster by requiring that the track matching χ^2 probability is $\chi^2 > 10^{-2}$.

4.4 Jet Reconstruction and Identification

Individual quarks and gluons cannot be detected directly due to color confinement. Instead, collimated streams of hadrons (*jets*) are observed in the detector. In this chapter we discuss the techniques that are used to reconstruct and identify jets.

4.4.1 Jet Cone Algorithm

The *Run II Midpoint Jet Cone Algorithm* is used to reconstruct jets for this analysis (37; 38). The general idea behind a jet cone algorithm is to define a cone in $\eta \times \Phi$ space, and to group together particles whose trajectories lie within that cone. After choosing an initial trial axis for a cone, the energy-weighted centroid is calculated based on contributions from all particles within the cone. Using the new cone axis, this process is iterated until a "stable" position is found, where the centroid of the energy depositions within the cone is aligned with the geometric axis of the cone.

Input into the algorithm can be based on calorimeter towers, in case the jet reconstruction is performed at the detector level in data or MC. Hadrons (partons) can be used as input at the particle (parton) level in MC.

The following is a description of the Run II Midpoint Jet Cone Algorithm:

1. Only *seed particles* with $p_T^{seed} > 1.0$ GeV are considered for jet reconstruction.

2. Cones are formed based on 4-vector variables (*E-scheme*):

$$p = (E, \mathbf{p}) = \sum_i (E^i, p_x^i, p_y^i, p_z^i,),\qquad(4.6)$$

$$p_T = \sqrt{(p_x)^2 + (p_y)^2}, \tag{4.7}$$

$$y = \frac{1}{2} \ln \frac{E + p_z}{E - p_z}, \tag{4.8}$$

$$\Phi = \tan^{-1} \frac{p_y}{p_x} \tag{4.9}$$

where p is the energy-momentum 4-vector of the cone, and the sum runs over all particles i within a cone of radius 0.5. p, y, and Φ define the centroid for a given cone. Each stable cone is added to a list of *proto-jets*. Only proto-jets with $p_T > 8.0$ GeV are considered.

3. Midpoints between any combination of two proto-jets are also used as seeds and iterated until stable cones are found. This is done to remove sensitivity to soft radiation (Figure 32, Reference (37)).

4. The proto-jets are checked for overlapping regions. In order to avoid double counting of energy a merging/splitting algorithm is applied. Two proto-jets are *merged* if the shared energy between them is greater than half of the lower p_T proto-jet. Otherwise, the two proto-jets are *split* and the tower energies are assigned to the closest proto-jet.

4.4.2 Jet Identification Parameters

A set of quality cuts is applied to every reconstructed jet, in order to reduce fake jets from calorimeter noise.

EM Fraction (EMF): Hadronic shower formation tends to distribute energy evenly in the EM and hadronic layers of the calorimeter, whereas EM objects mostly shower in the EM
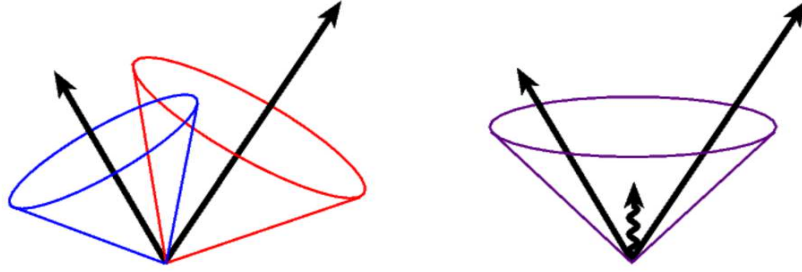

Figure 32. Illustration showing how the presence of soft radiation between two jets may cause a merging of the jets (right) that would not occur in the absence of the soft radiation (left).

layers. Therefore, a cut on the fraction of transverse energy in the EM layers distinguishes jets from EM objects.

Coarse Hadronic Fraction (CHF): Coarse hadronic fraction is the fraction of transverse energy of a jet that is deposited in the coarse hadronic layers of the calorimeter.

Hot Fraction (HotF): Hot Fraction is the ratio of transverse energy in the most energetic tower to that of the next most energetic tower in the jet. If a significant amount of the total jet energy is originating from a single calorimeter tower, it is likely that the tower is generating artificially high read-out signals due to detector problems (*hot tower*). A cut on the Hot Fraction parameter eliminates jets originating from hot towers.

N90: N90 is the number of towers making up 90% of the jet energy. A cut on the N90 parameter eliminates jets originating from hot towers as well.

L1 Confirmation: L1 confirmation was introduced in order to deal with calorimeter cell precision readout noise. The jet energy at the L1 trigger tower level is compared with the jet energy derived from the jet cone algorithm, which is based on calorimeter cell precision readout:

$$L1conf = \frac{\sum_{trigger} E_T^i}{E_T^{jet} \cdot (1 - CHF)} \tag{4.10}$$

where $\sum_{trigger} E_T^i$ is the sum of transverse TOT trigger tower energies within $\Delta R < 0.5$ of the reconstructed jet; E_T^{jet} is the transverse energy of the reconstructed jet; and CHF is the Coarse Hadronic Fraction of the reconstructed jet.

4.4.3   Jet Energy Scale

The jet energy scale (JES) is a calibration that adjusts the measured jet energy for various effects (39). Depending on the jet E_T and jet η, the JES applies a calibration factor that allows to obtain the particle level jet E_T ($E_{jet}^{particle}$) from the measured jet E_T ($E_{jet}^{calorimeter}$) according to the following relation:

$$E_{jet}^{particle} = \frac{E_{jet}^{calorimeter} - E_{offset}}{R_{jet} \cdot R_{cone}} \tag{4.11}$$

where E_{offset} is the *offset energy*, R_{jet} is the *jet response* correction, and R_{cone} is the *out of cone showering* correction.

Offset Energy: Any energy contributions to the jet reconstruction which are not related to the physics processes that are responsible for creating a jet need to be subtracted from the measured jet energy. The offset energy term contains contributions from multiple

interactions, underlying event energy, electronic noise, uranium noise, and pile-up from previous bunch crossings.

Jet Response: The jet response correction takes into account the calorimeter response to hadronic jets, i.e. the amount of energy that is lost due to uninstrumented regions and dead material in the calorimeter. The correction is estimated from the p_T imbalance in back-to-back photon+jet events, by taking advantage of the fact that photon E_T can be measured to a high level of accuracy.

Out of Cone Showering: It is possible that some particles produced inside (outside) the jet algorithm cone deposit a fraction of their energy outside (inside) of the cone. This is due to interactions between detector material and the particles that comprise a jet. Additionally, particle trajectories can bend in the magnetic field, which may lead to energy being deposited inside or outside of the jet cone.

CHAPTER 5

MONTE CARLO EVENT SIMULATION

MC event simulations are an essential tool in particle physics (40; 41). The simulations represent our theoretical understanding of nature, and the ultimate goal is to simulate nature as accurately as possible. In particle physics, MC simulations include all stages of interactions that occur at particle accelerators including initial creation of partons in hadronic collisions (*parton level*), subsequent hadronization (*particle level*), and simulations of detector responses (*detector level*). Therefore, MC event simulations compare MC output with data in order to test theoretical predictions. The simulations can also be used to estimate detector acceptances and to study background processes. Alternatively, the simulations permit to correct data for detector effects so that direct comparisons to generator level MC simulations can be made.

This chapter gives a description of the MC simulation tools and techniques, that were used in this analysis.

5.1 The PYTHIA Event Generator

PYTHIA is a general purpose MC event generator (42) which describes most physical aspects of a typical high-energy event:

1. The initial beam particles, such as protons and antiprotons, are characterized by PDFs.

2. One parton from each initial particle starts to radiate through a *Bremsstrahlung*-like process, such as $q \rightarrow qg$, to initiate a sequence of branchings which builds up an initial-state shower (*Initial State Radiation*, or ISR).

3. Two partons participate in the *hard process* which produces a number of outgoing particles. PYTHIA is optimized for hard processes that have two particles in the initial and final states, such as $q\bar{q} \rightarrow Z/\gamma^* \rightarrow e^+e^-$ ($2 \rightarrow 2$ *process*). Intermediate resonances, like Z/γ^*, need to be included in the description of the hard process.

4. Final state particles can also radiate to initiate a final-state shower (*Final State Radiation*, or FSR).

5. The remaining partons (*spectators*) in the two incoming hadrons may interact.

6. Beam remnant interactions are taken into account.

7. Outgoing quarks and gluons are forming color neutral hadrons due to QCD confinement.

8. Many of the produced hadrons are unstable and decay further.

In order to describe inclusive $Z/\gamma^* \rightarrow e^+e^-$ events, we use a PYTHIA sample based on the $q\bar{q} \rightarrow Z/\gamma^* \rightarrow e^+e^-$ hard process, where the LO cross section is due to the electroweak interaction. ISR parton showers provide QCD corrections to the LO calculation. Figure 33 shows an illustration of a parton shower (9). The probability for a parton to radiate, or branch, is given by the *DGLAP* or *Altarelli-Parisi* equation (43; 44; 45). First, we introduce

$$t = \ln(Q^2/\Lambda^2) \quad \Rightarrow \quad \mathrm{d}t = \mathrm{d}\ln(Q^2) = \frac{\mathrm{d}Q^2}{Q^2} \tag{5.1}$$

where Q is the scale of the hard process, and Λ is the scale at which α_s becomes large and non-perturbative QCD becomes important. The differential probability for parton a to branch is now

$$\mathrm{d}\mathcal{P}_a = \sum_{b,c} \frac{\alpha_s}{2\pi} \ P_{a \to bc}(z) \ \mathrm{d}t \mathrm{d}z \qquad (5.2)$$

where a branches according to $a \to bc$, with parton b taking a fraction z of the energy and momentum of a. The splitting kernels $P_{a \to bc}(z)$ express the probabilities for different branchings, and the sum runs over all allowed branchings ($q \to qg$, $g \to q\bar{q}$, etc.). The parameter t can be regarded as describing the time for the shower evolution. In this picture, the actual probability that a branching of a occurs at t can be expressed as the naive answer modified by an exponential suppression; if a parton has already branched at a 'time' $t' < t$, it can no longer branch at t. This description is analogous to the radioactive decay problem. In the parton-shower language, the exponential factor is known as the *Sudakov form factor*. PYTHIA uses this 'radioactive decay' type description and applies it to the parton-shower evolution.

The parton shower is evolved from the scale Q down to a cut-off scale Q_0 where it terminates. At this scale, QCD becomes strongly interacting and perturbation theory breaks down. Due to confinement, the colored partons are converted into colorless hadrons by the hadronization process. PYTHIA uses a phenomenological model known as the *String Model* to describe this process. As a color-confined quark-antiquark pair moves out in opposite directions, the color field between them collapses into a string-like configuration, where each string has a uniform energy per unit length, and the potential energy in the string increases as the quarks move apart. Once the potential becomes energetically favorable another $q\bar{q}$ pair is pulled from the
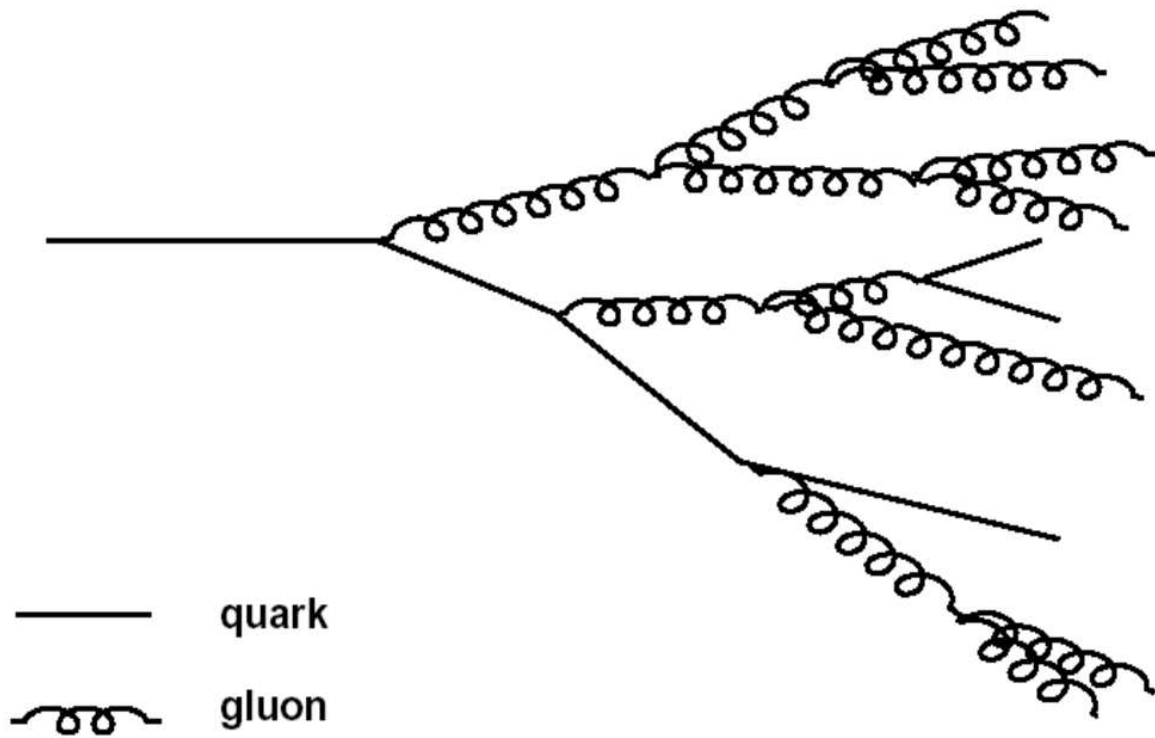

Figure 33. Schematic view of a parton shower.

vacuum, and the string split into two. This process continues until only on mass-shell hadrons remain.

5.2   Combining Matrix Elements with Showering

PYTHIA is essentially based on the differential cross section for a simple $2 \to 2$ process, and then combined with a parton-shower simulation of additional QCD radiation that connects to a model of hadronization in order to account for multijet events. Since parton showers are only reliable approximations in the limits of low p_T and small emission angles (*soft* and *collinear limits*), final states with several hard and well separated jets are not properly described. Such final states occur frequently at the Tevatron due to the large energies that are available. Therefore, different MC generators are needed to estimate multijet cross sections by calculating the corresponding partonic matrix elements. In order to obtain results that can be compared to experimental data, these calculations are completed by taking into account higher-order corrections from parton showers. The consistent combination of the parton level calculations with the partonic evolution due to the MC shower simulation, as implemented in PYTHIA, is the subject of extensive work (46; 47).

One of the biggest problems when combining matrix element and parton shower event generators is the potential for *double counting* jet configurations. Consider a process like $q\bar{q} \to Z$ together with its higher order companion process $q\bar{q} \to Zg$. Some fraction of the higher order process is described by the lower order process through gluon ISR. Therefore, the two processes can not be simply combined, since this would lead to double counting of some portion of phase space. On the other hand, simply ignoring the higher order process would lead to a poor description of high p_T Z bosons.

A solution to this problem has been proposed by Catani, Krauss, Kuhn, and Webber

($CKKW$) (48). In this approach the phase space for a n parton process is devided into a matrix element regime and a parton shower regime, by using the parameter y_{cut}. Kinematics in the parton shower regime are based on $n-1$ partons. While the parton shower develops, possible branchings can be *vetoed* by re-weighting the matrix elements with Sudakov form factors. This prevents the shower regime from populating the matrix element regime. Since y_{cut} introduces an arbitrary scale, physical observables will be dependent on this parameter. However, this dependence is small when following the CKKW scheme.

5.2.1 Combining ALPGEN with PYTHIA

In order to describe inclusive $Z/\gamma^* \to e^+e^- + \geq n$ jet events ($n \geq 1$), we use the tree-level matrix element generator ALPGEN (49; 50). ALPGEN was designed to simulate specific SM processes in hadronic collisions, emphasizing large jet multiplicities in the final state. ALPGEN calculates parton level final states to lowest order in perturbation theory. The ALPGEN output is interfaced with PYTHIA for showering and hadronization.

No procedure to avoid double counting of jet configurations is implemented in the ALPGEN + PYTHIA samples used for this analysis. While it is still possible to use these samples to compare the shape of basic kinematic variables, they can not be used to estimate cross sections.

5.2.2 Combining MADGRAPH with PYTHIA

MADGRAPH (51) is a tree-level matrix element generator, and it is based on specifying initial and final state particles for arbitrary processes. It then creates a list of all relevant Feynman diagrams and calculates the corresponding matrix elements. The program is able to

calculate matrix elements for any SM process. The only limitation is processing power[1]. The MADGRAPH output is interfaced with PYTHIA for showering and hadronization.

The matching between MADGRAPH and PYTHIA in order to avoid double counting is done following a modified CKKW prescription (see (52; 53) for details). We refer to these samples as *CKKW samples* and use them for the final cross section comparison.

5.3   The MCFM Monte Carlo Simulation

MCFM (*Monte Carlo for FeMtobarn processes*) (54; 55; 56) is a parton-level event generator with at most three partons in the final state. It calculates partonic cross sections to NLO in α_s, which reduces the dependence of the cross sections on the renormalization and factorization scales. No parton showering or hadronization is available for MCFM at this time.

We compare our final results to MCFM cross sections.

5.4   The DØ Detector Simulation

After all final state particles are generated, detector effects can be simulated with a simulation package called D0GSTAR (*D0 GEANT Simulation of the Total Apparatus Response*) (57). D0GSTAR is based on the CERN package GEANT (*GEometry ANd Tracking*) (58) which simulates the passage of particles through matter. Effects such as ionization, showering, and magnetic field interaction in the DØ detector are modeled. The output of this simulation has the same format as the real data recorded by the detector. The full event reconstruction applied to real data can also be applied to the simulation output for direct comparisons.

---

[1]At present MADGRAPH is limited to 10,000 diagrams per subprocess, corresponding to $W+$ 5 jets.

CHAPTER 6

DATA AND MONTE CARLO SAMPLES

This chapter gives a description of the data and MC samples in Sections 6.1 and 6.2. Event selection criteria are discussed in Section 6.3. Section 6.4 compares basic properties of electrons and jets between data and MC.

6.1   Data Sample

The dataset used for this analysis was collected between April 2002 and June 2004 and contains approximately 1 billion events. We process the raw data with the p14 version of the DØ reconstruction software. In order to create a final data sample of manageable size, we apply additional pre-selection or *skimming* criteria:

EM1TRK skimming We require that each event in the data set has at least one EM object with ID = 10 or ±11, $p_T > 8$ GeV, and a track with $p_T > 5$ GeV within $\Delta\phi = 0.1$ of the EM object. These requirements reduce the size of the data sample to approximately 57 million events.

Root-tuple creation The reconstructed data are reformatted into an object oriented ntuple format (*root-tuple*) using the ATHENA (59) software package (version p16-br-03). At this stage, JES corrections (version 5.3) and a calorimeter noise suppression algorithm (T42 (60)) are applied.

Root-tuple skimming The root-tuple data are further skimmed by requiring at least one

EM object with EM fraction > 0.9, Isolation< 0.15, H-Matrix(7)< 12.0, $|\eta_{det}| < 1.1$ and

a track match[1] in each event. The final analysis root-tuple contains 2.4 million events.

Data flagged as unusable by data-quality experts is excluded from the analysis. We require

that the SMT, CFT, calorimeter, and luminosity subsystems of the detector are fully opera-

tional. Additionally all data taking periods with limited L1CAL trigger coverage ($|\eta| < 0.8$)

are excluded (61).

Events for the analysis are selected based on the requirement that the trigger system iden-

tifies at least one EM object (*single electron triggers*). Additionally, the single electron triggers

are *unprescaled*. In case that the trigger conditions implemented in the trigger system during

data taking are not providing the required reduction in event rate, *prescaling factors* are ap-

plied. For example, if a prescaling factor of 3 is applied to a given trigger, then only one out

of three proton-antiproton bunch crossings is considered for evaluation by the trigger system.

In order to maximize the amount of luminosity available, all events in the analysis met the

unprescaled trigger condition.

The data taking period for this analysis can be divided into two periods during which dif-

ferent lists of single EM triggers were implemented. The following is the prioritized order of

---

[1]χ^2 probability for best track using the distance in η/Φ and E/p

trigger combinations for trigger lists before *global_CMT-12* (runs $\leq$ 178732, "pre-v12 dataset")[1]

(62):

- EM_HI_SH or EM_HI_2EM5_SH

- EM_HI_SH

- EM_HI

- EM_MX_SH

- EM_MX

The Level 2 trigger subsystem was not available for the entire pre-v12 dataset (all runs with run numbers $\leq$ 169523) in which case we do not require the Level 2 trigger condition to be satisfied.

The trigger combinations for trigger list *global_CMT-12* (runs $\geq$ 178722, "v12 dataset") are:

- E1_SHT20 or E2_SHT20 or E3_SHT20 or E1_SH30

- E1_SHT20 or E2_SHT20 or E1_SH30

- E1_SHT20 or E1_SH30

- E1_SHT20

Table I contains details of the individual triggers.

A total integrated luminosity of 343 pb^{-1} was available for this analysis after trigger selection and exclusion of unusable data due to bad quality.

---

[1]The statement "Trigger A or Trigger B" refers to the fact that we accept a given event, if Trigger A and Trigger B are unprescaled, and the trigger requirements for either Trigger A or Trigger B are met.

TABLE I

SINGLE EM TRIGGERS USED IN THIS ANALYSIS

Trigger	L1	L2	L3

EM(1,12)	one EM candidate with $E_T > 12$ GeV (not present for runs below 169524)

L3 Triggers	
ELE_LOOSE_SH_T(1,20)	one electron with $|\eta| < 3.0$ and $E_T > 20$ GeV passing loose requirements including shower shape cuts
ELE_LOOSE(1,30)	one electron with $|\eta| < 3.0$ and $E_T > 30$ GeV passing loose requirements
ELE_NLV_SHT(1,20)	one electron with $|\eta| < 3.6$ and $E_T > 20$ GeV passing tight shower shape cuts
ELE_NLV_SH(1,30)	one electron with $|\eta| < 3.6$ and $E_T > 30$ GeV passing loose shower shape cuts

6.2   Monte Carlo Samples

6.2.1   PYTHIA and ALPGEN Samples

The MC samples used for data to MC comparisons and acceptance estimations are summarized in Table II. For studies regarding the inclusive $Z/\gamma^* \to e^+e^-$ cross section, a PYTHIA $Z/\gamma^* \to e^+e^-$ inclusive sample is used. For higher jet multiplicities, events are generated with ALPGEN and then passed through PYTHIA for parton showering and hadronization ($\mu_{F/R}^2 = M_Z^2 + \sum p_{Tjet}^2$). Since the electron energy resolution in data is not correctly described by the MC simulation, additional energy smearing is applied to the MC electrons. The p_T (as well as p_x, p_y, p_z and Energy) of the electrons is replaced by $p_T \to p_T \cdot c \cdot \text{Gauss}(1, f)$ where Gauss(1,f) is the smearing parameter which is randomly chosen from a Gaussian distribution with mean 1 and width f. c is an overall calibration factor. We use the following values for the smearing parameters (63):

- f = 0.045

- c = 1.003

We also apply jet resolution smearing to the MC jets based on the jet resolution in data and MC derived with JES version 5.0 (applying T42)(64). Equation 6.1 shows the resolution

parameterization where the constants C, S, and N represent the calibration errors, sampling fluctuations, and noise contributions respectively.

$$\frac{\sigma(p_T)}{p_T} = \sqrt{\frac{N^2}{p_T^2} + \frac{S^2}{p_T} + C^2} \qquad (6.1)$$

Table III summarizes all coefficients for different detector regions.

Using the p_T and η_{det} of the MC jets, we calculate the data and MC resolutions. If the data resolution is better than the MC resolution for a given jet, we do not apply any additional smearing. If the resolution is worse in data than in MC, we calculate a multiplicative smearing factor (Equation 6.2) and apply it to the p_T of the jet.

$$\text{Smearing Factor} = \text{Gauss}\left(1, \sqrt{\left(\frac{\sigma(p_T)}{p_T}\right)^2_{data} - \left(\frac{\sigma(p_T)}{p_T}\right)^2_{MC}}\right) \qquad (6.2)$$

Process	Generators	Size
$Z(\gamma^*) \to e^+e^-$	PYTHIA	400k
$Zj \to e^+e^-j$	ALPGEN + PYTHIA	150k
$Zjj \to e^+e^-jj$	ALPGEN + PYTHIA	180k

TABLE III

JET RESOLUTION PARAMETERS IN DATA AND MC.

6.2.2 CKKW Samples

Table IV summarizes the CKKW samples that are used. The samples use a matching threshold of $p_T > 15$ GeV. Jets are generated with $|\eta| < 2.5$. The Z boson has a generated mass between 75 GeV and 105 GeV. The matrix element generation with MADGRAPH was done up to jet multiplicities of 3. Higher jet multiplicities are due to parton showering and hadronization simulated with PYTHIA. The factorization scale is set to $\mu_F^2 = M_Z^2$. The renormalization scale is set to $\mu_R^2 = p_{Tjet}^2$ for jets from initial state radiation and $\mu_R^2 = k_{Tjet}^2$ for jets from final state radiation.

6.2.3 MCFM Cross Sections

MCFM inclusive cross sections are calculated for up to 3 jets. The kinematic and geometric jet cuts are the same as used in the analysis: jet $p_T > 20$ GeV, $|\eta| < 2.5$. The Z boson has a mass between 80 GeV and 100 GeV, and CTEQ6M is used for the PDF. The renormalization and factorization scales are set to $\mu_{F/R}^2 = M_Z^2 + p_{TZ}^2$.

Process	Generators	Size

TABLE IV

LIST OF CKKW SAMPLES

6.3   Event Selection

The following selection criteria are applied in order to assure that we select events with two high p_T electrons contained within the central calorimeter and originating from the decay of a Z/γ^* gauge boson. After identifying these *Z candidate* events, we require the presence of n high p_T jets.

6.3.1   Primary Vertex

The efficiency to reconstruct the PV is about 100 % in the central region of the detector, and quickly drops outside the SMT fiducial volume. Therefore, we require that the PV is within 60 cm of the detector center along the beam pipe (z-axis).

6.3.2   Electron Selection

EM objects have to satisfy the following requirements:

- Loose electrons:

    - ID = 10 or ± 11

- – EM Fraction > 0.9

- – Isolation < 0.15

- – H-Matrix(7) < 12

- – $p_T > 25$ GeV

- – $|\eta_{det}| < 1.1$

- Tight electrons:

  - – Requirements of loose electron.

  - – Track match[1] with $P(\chi^2) > 0.01$

6.3.3 Z Selection

Z candidates are selected based on the following criteria:

- Two loose electrons.

- At least one of the two electrons needs to be tight.

- One of the two electrons must have fired the trigger.

- Diem invariant mass window cut: 75 GeV $< M_{ee} < 105$ GeV

6.3.4 Jet Selection

Jets are formed using a simple cone jet algorithm with a cone size of 0.5 and are selected based on the following criteria:

---

[1]χ^2 probability for best track using the distance in η/Φ and E/p

- $0.05 < \text{EMF} < 0.95$

- HotF < 10.

- N90 > 1.

- CHF < 0.4

- L1 confirmation

- JES corrected $p_T > 20$ GeV

- $|\eta_{physics}| < 2.5$

- Since the jet algorithm identifies *fake* jets originating from electron energy deposits, we remove all jets overlapping with electrons coming from the Z/γ^* boson within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ of 0.4.

6.3.5   Event Statistics

Table V summarizes the number of $Z/\gamma^* \rightarrow e^+e^-$ event candidates for different exclusive jet multiplicities.

6.4   Data vs Monte Carlo

This section presents a comparison of basic kinematic distributions for electrons, Z candidates, and jets between data and MC simulations. It is important that the MC distributions describe the data distributions as accurately as possible. The MC simulations are used to account for the fraction of events that are lost due to kinematic and geometric electron cuts, the diem invariant mass cut, and the primary vertex cut (*acceptance*).

Sample	N	Fraction
$Z/\gamma^* + 0$ jets	12,247	0.8815
$Z/\gamma^* + 1$ jets	1,427	0.1027
$Z/\gamma^* + 2$ jets	189	0.0136
$Z/\gamma^* + 3$ jets	25	0.0018
$Z/\gamma^* + 4$ jets	3	0.0002
$Z/\gamma^* + 5$ jets	2	0.0001
Total	13,893	1.0000

TABLE V

EVENT BREAKDOWN BY EXCLUSIVE JET MULTIPLICITIES ASSOCIATED WITH Z/γ^* PRODUCTION BEFORE ANY BACKGROUND IS SUBTRACTED OR ANY CORRECTIONS ARE APPLIED.

6.4.1 Primary Vertex Comparison

Figure 34 compares the primary vertex distribution between data and inclusive $Z/\gamma^* \to e^+e^-$ PYTHIA MC.

6.4.2 Z p_T Comparisons

Figure 35 shows the Z p_T comparison between data and PYTHIA MC. Since PYTHIA does not fully incorporate higher-order contributions of hard radiation to the Drell-Yan (γ^*) process, there is a disagreement on the Z p_T distribution (especially at high p_T) with the data. To account for this discrepancy, an additional correction based on the Z p_T comparison between data and MC is applied. The Z p_T correction is also shown in Figure 35.

Figure 36 and Figure 37 show Z p_T comparisons when using ALPGEN + PYTHIA for

CHAPTER 7

MEASUREMENT OF THE $Z/\gamma^*(\to e^+e^-)$ INCLUSIVE CROSS SECTION

In order to determine the $Z/\gamma^*(\to e^+e^-)$ inclusive cross section, we evaluate the following equation:

$$\sigma \times \mathrm{BR}(Z/\gamma^* \to e^+e^-) = \frac{N-B}{\mathcal{L} \times \varepsilon}. \tag{7.1}$$

$N-B$ is the number of signal events which is estimated from the diem invariant mass histogram after background subtraction. The primary background is from multi-jet production from QCD processes in which the jets have a large electromagnetic component or are mismeasured in such a way that the jets pass the electron selection criteria. The shape of the QCD background in the diem invariant mass histogram follows an exponential distribution.

Our goal is to measure the cross section for diem pairs where both γ^* (*Drell-Yan*) and Z boson exchange contribute. Contributions from pure Z boson decays will show up as a peak around the Z mass at $\approx$91 GeV in the diem invariant mass histogram. The Drell-Yan component follows an exponential distributions.

The total integrated luminosity of the dataset $\mathcal{L}$ is approximately 343 pb^{-1}.

The efficiency ε to measure e^+e^- pairs resulting from Z/γ^* decays can be factorized according to:

$$\varepsilon_{tot} = \varepsilon_{trigger} \cdot \varepsilon_{EM} \cdot \varepsilon_{track} \cdot \varepsilon_{acceptance} \tag{7.2}$$

where $\varepsilon_{trigger}$ is the efficiency of the event to have at least one electron to pass all trigger levels, ε_{EM} is the efficiency of reconstructing two EM clusters which pass all electron ID cuts, ε_{track} is the efficiency of finding at least one track which matches an EM cluster and $\varepsilon_{acceptance}$ is the efficiency of the kinematic and geometric electron cuts, the diem invariant mass cut and the primary vertex cut. Practically, we apply all efficiencies (except for $\varepsilon_{acceptance}$) as corrections to the diem invariant mass histogram. This procedure is outlined in the following chapters.

7.1   Efficiencies

7.1.1   Trigger Efficiency

The combined efficiency of all triggers per electron is studied with a *tag-and-probe method* using Z candidate events with invariant mass between 70 and 110 GeV. For this method, both Z candidate electrons are considered as possible "tags". An electron becomes a "tag" if it passes trigger requirements for at least one unprescaled trigger in the trigger combination. To pass the requirements of a trigger, an electron must have a matching trigger object at each level which passes all cuts for the corresponding trigger. Both the tag and probe electrons must satisfy the following requirements:

- $p_T > 20$ GeV

- EM Fraction > 0.9

- Isolation < 0.15

- H-Matrix(7) < 12

- Track match with $P(\chi^2) > 0.01$

The probe electron must have matching trigger objects at L1, L2 and L3 within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ of 0.4.

Trigger efficiencies are parameterized versus EM object p_T and derived separately for pre-v12 and v12 data. In cases where the L2 subsystem was not operative (all runs with run numbers $\leq$ 169,523) only L1 and L3 trigger objects were used. The average trigger efficiencies for the pre-v12 and v12 datasets are (with statistical errors):

- $\varepsilon_{pre-v12}(\text{Trigger}) = 94.6\% \pm 0.3\%$

- $\varepsilon_{v12}(\text{Trigger}) = 98.2\% \pm 0.1\%$

Figure 49 shows the parameterized trigger efficiencies for both datasets.

We correct for trigger inefficiencies in the following way:

- In a given event we use the trigger efficiency curves to get the trigger efficiencies ε_1 and ε_2 for the two EM objects (based on p_T).

- To get the event based trigger efficiency, we need to take into account all permutations for the two EM objects to fire a trigger:

$$\varepsilon_{trigger} = \varepsilon_1 \cdot (1 - \varepsilon_2) + \varepsilon_2 \cdot (1 - \varepsilon_1) + \varepsilon_1 \cdot \varepsilon_2 = \varepsilon_1 + \varepsilon_2 - \varepsilon_1 \cdot \varepsilon_2 \qquad (7.3)$$

- The inverse of $\varepsilon_{trigger}$ is applied as a corrective weight when we fill the diem invariant mass histogram.

- We use the corrected diem invariant mass histogram to derive the number of signal events for the cross section calculation.
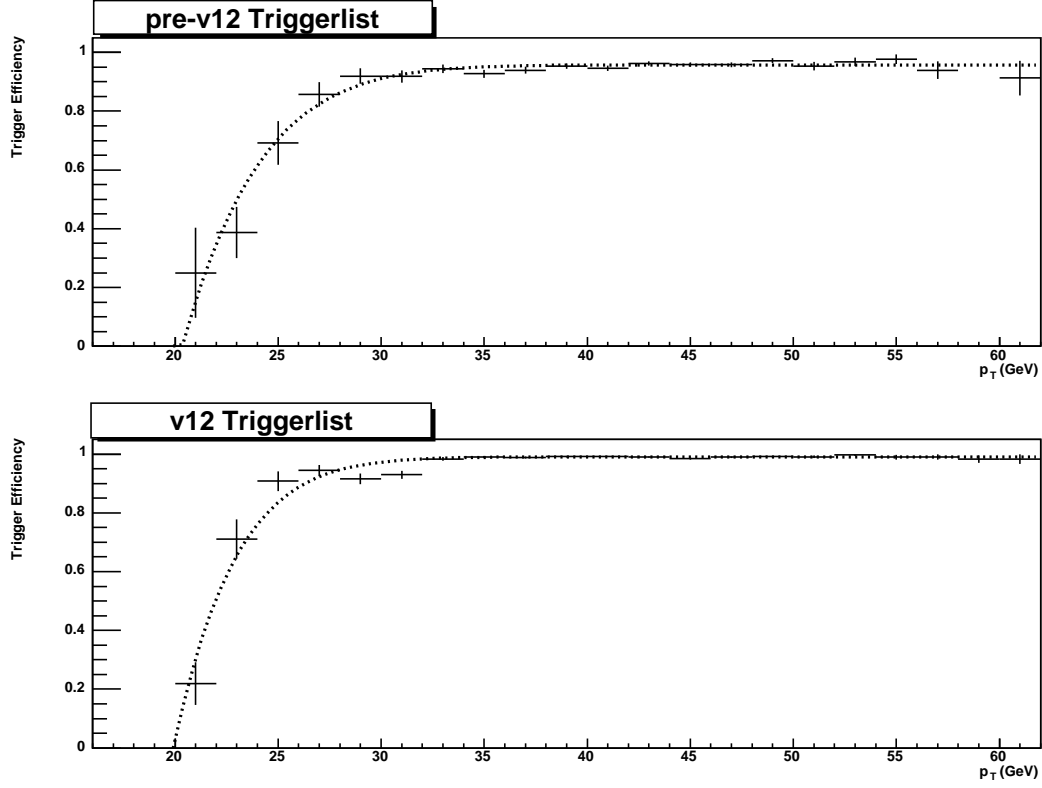

Figure 49. Trigger efficiencies for pre-v12 (top) and v12 (bottom) datasets vs EM object p_T

7.1.2 EM Reconstruction and Identification Efficiency

To determine EM efficiencies, a tag and probe method is used. The tag leg consists of an electron candidate, and the probe leg consists of a track. The tag electron must pass all the loose electron selection cuts, have a matched track and satisfy trigger requirements for the event. Both tag and probe tracks must satisfy the following selection criteria (65):

- Stereo track[1]

- 25 GeV $< p_T <$ 80 GeV

- χ^2 probability for best track < 8 (using the distance in η/Φ and E/p)

- Distance of closest approach between track and beam position in the R-Φ plane < 0.3 cm

- Δz_{vertex} of the two tracks < 4 cm

- $|\eta_{detector}| < 1.1$

Tag electron selection criteria:

- ID $= 10$ or ± 11

- EMFraction > 0.9

- Isolation < 0.15

- H-Matrix(7) < 12

- $p_T > 25$ GeV

- $|\eta_{det}| < 1.1$

- No fiducial restrictions in ϕ.

- Matched with tag track within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = \sqrt{0.1^2 + 0.1^2} = 0.14$.

- Must have fired the trigger.

---

[1]Requiring hits in stereo layers of the tracking system (see Chapter 3.3.2).

We reduce possible background contamination by requiring that tag- and probe-tracks have opposite signs, and imposing a cut on the missing transverse energy of the event (missing $E_T < 15$ GeV). Additionally we require:

- $|PVZ| < 60$ cm

- Tag-electron-probe-track invariant mass cut: 70 GeV $< M_{ee} < 110$ GeV

Once an event is found which satisfies all of the above requirements, a denominator histogram is filled. We use (probe track) ϕ and p_T histograms for parameterized efficiencies and tag-electron-probe-track diem invariant mass histograms for average efficiencies. If a reconstructed EM cluster is found nearby the probe-track ($\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = \sqrt{0.1^2 + 0.1^2} = 0.14$) which passes the EMID cuts (HMx, EMF, Iso), the respective numerator histogram is filled.

Since average efficiencies are derived from diem invariant mass histograms, we can apply an additional step to subtract background. We estimate the background in the sidebands of the diem invariant mass distributions, and extrapolate it into the signal region where it is subtracted. The average EM reco and ID efficiencies in data and MC are (with statistical errors):

- $\varepsilon_{data}(\text{EM}) = 88.9\% \pm 0.3\%$

- $\varepsilon_{MC}(\text{EM}) = 93.1\% \pm 0.1\%$

The sideband background subtraction cannot be applied in the case of parameterized efficiencies. We cross check the level of background contamination by deriving the average efficiency in data without the sideband background subtraction. The result is within 1% of the sideband

subtracted value: $88.2\% \pm 0.2\%$.

Figure 50 and Figure 51 show the EM efficiencies for data and MC in a one-dimensional parameterization versus probe track Φ and p_T. Note that the central calorimeter has narrow uninstrumented regions between the azimuthal module boundaries (*phi cracks*). An EM object entering the calorimeter near these boundaries can lose a portion of its energy in these cracks, which results in decreased EM efficiencies for these regions.

We correct for the EM inefficiencies in the following way:

- In a given event we use two-dimensional efficiency curves (versus p_T and Φ) to estimate the EM efficiencies ε_1 and ε_2 for the two EM objects (based on their p_T and Φ).

- To estimate the event based EM efficiency we take the product of ε_1 and ε_2:

$$\varepsilon_{EM} = \varepsilon_1 \cdot \varepsilon_2 \tag{7.4}$$

- The inverse of ε_{EM} is applied as a corrective weight when we fill the diem invariant mass histogram.

7.1.3 EM-Track Match Efficiency

Average track finding and matching efficiencies are derived using diem invariant mass histograms (Figure 52 to Figure 55).

Using a convolution of a Gaussian and Breit-Wigner fit for the Z peak and an exponential shape to describe the QCD and Drell-Yan contributions, we extract the number of events under the Z peak from the four diem invariant mass histograms: $N_{1trk}(data)$, $N_{2trk}(data)$, $N_{1trk}(MC)$
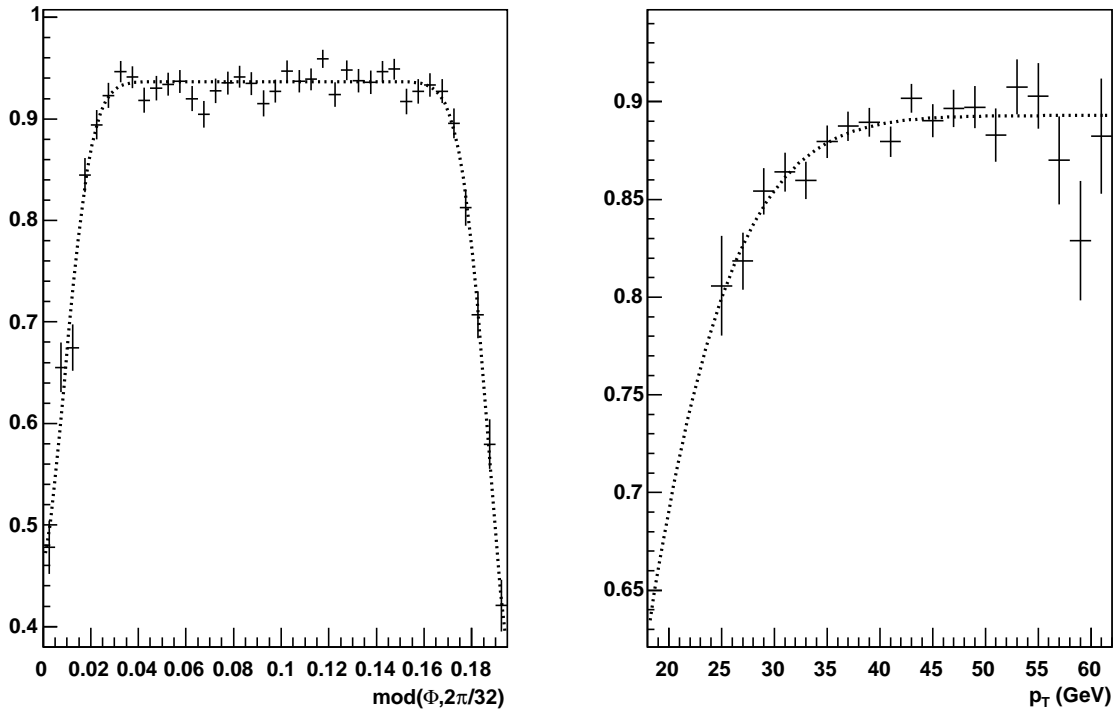

Figure 50. EM efficiencies versus probe track Φ and p_T in data. The Φ distribution shows the modulus(Φ, $\frac{2\pi}{32}$) distribution to illustrate the effect of the calorimeter Φ-module boundaries.
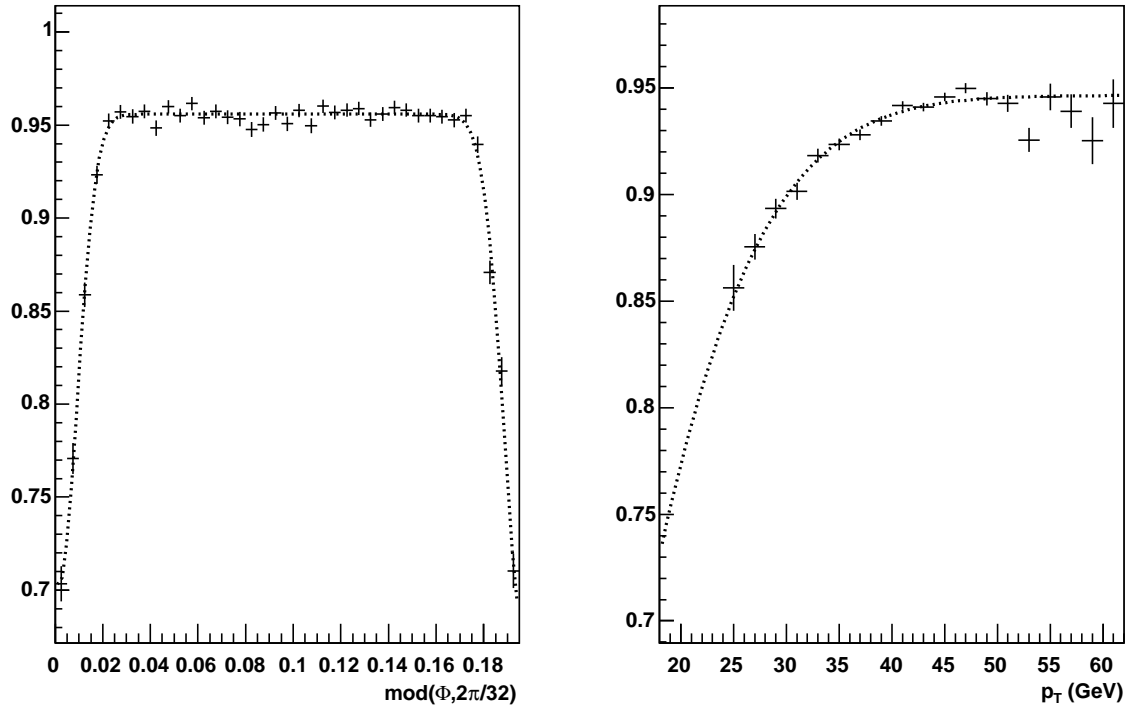

Figure 51. EM efficiencies versus probe track Φ and p_T in MC. The Φ distribution shows the modulus(Φ, $\frac{2\pi}{32}$) distribution to illustrate the effect of the calorimeter Φ-module boundaries.

and $N_{2trk}(MC)$. $N_{1trk}(data)$ and $N_{1trk}(MC)$ are the number of Z candidates when requiring at least one track match in data and MC; $N_{2trk}(data)$ and $N_{2trk}(MC)$ are the number of Z candidates when requiring exactly two track matches in data and MC. We use these numbers to estimate the average track finding and matching efficiencies in data and MC:

$$\varepsilon_{data}(\text{Tracking}) = \frac{2 \cdot N_{2trk}(data)}{N_{2trk}(data) + N_{1trk}(data)} = 77.1\% \pm 0.3\% \qquad (7.5)$$

$$\varepsilon_{MC}(\text{Tracking}) = \frac{2 \cdot N_{2trk}(MC)}{N_{2trk}(MC) + N_{1trk}(MC)} = 87.8\% \pm 0.03\% \qquad (7.6)$$

We correct for the tracking inefficiencies in the following way:

- In each event we use the average tracking efficiency $\varepsilon_{average}$ (Equation 7.5 and Equation 7.6).

- To get the event based tracking efficiency we need to take all permutations for one or two tracks into account:

$$\varepsilon_{tracking} = 2 \cdot \varepsilon_{average}(1 - \varepsilon_{average}) + \varepsilon_{average}^2 = 2 \cdot \varepsilon_{average} - \varepsilon_{average}^2 \qquad (7.7)$$

- The inverse of $\varepsilon_{tracking}$ is applied as a corrective weight when we fill the diem invariant mass histogram.

7.1.4 Acceptance

We use the $Z/\gamma^* \to e^+e^-$ PYTHIA MC sample to estimate the acceptance. The numerator contains the number of events satisfying the following requirements at the reconstructed level:
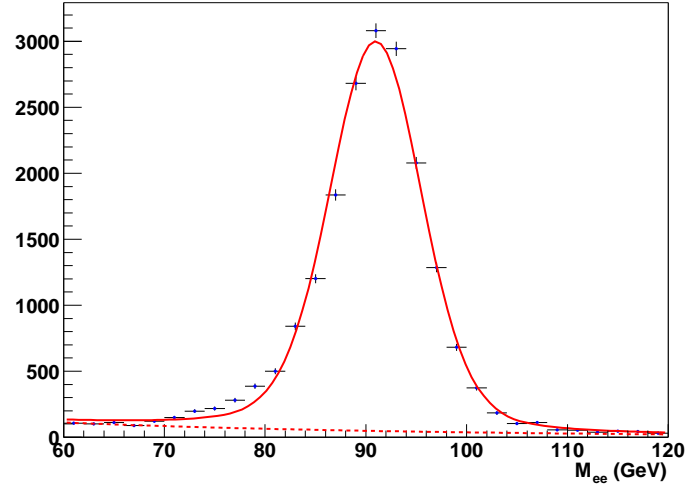

Figure 52. Invariant mass in data when requiring at least one track-matched electron.
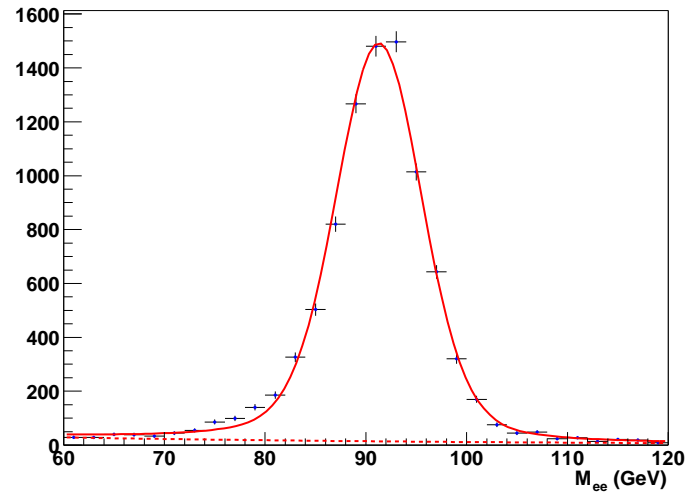

Figure 53. Invariant mass in data when requiring two track-matched electrons.
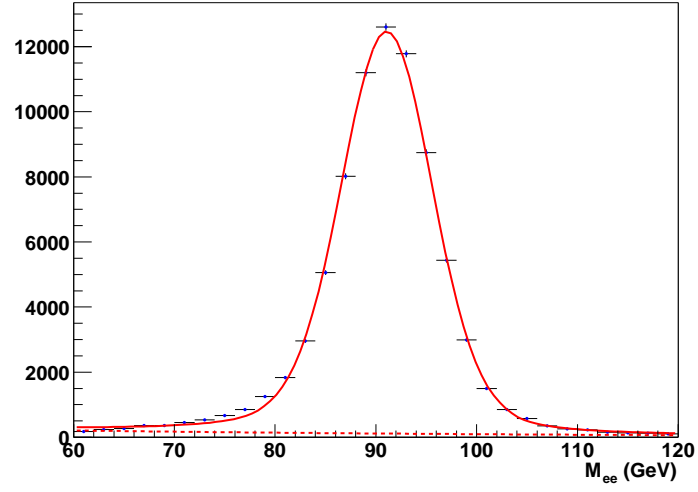

Figure 54. Invariant mass in MC when requiring at least one track-matched electron.
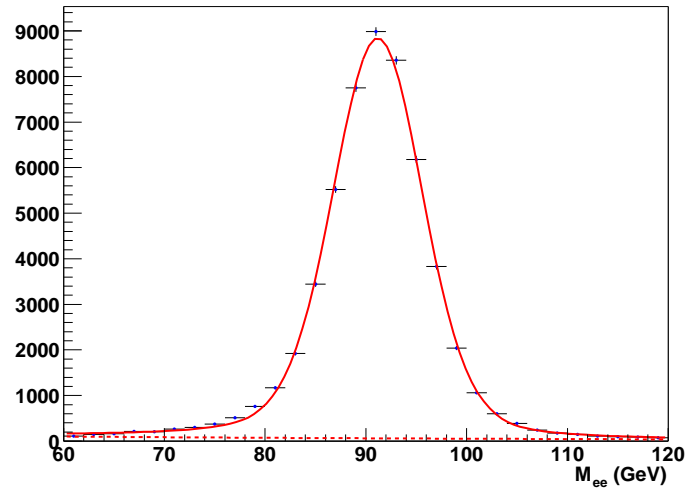

Figure 55. Invariant mass in MC when requiring two track-matched electrons.

- Primary vertex cut: $|PVZ| < 60$ cm

- Electron cuts: $p_T > 25$ GeV and $|\eta| < 1.1$

- Diem invariant mass cut: 75 GeV $< M_{ee} < 105$ GeV

The denominator contains the number of events with generated Z/γ^* particles that are within the diem invariant mass window.

We estimate the acceptance with statistical error for inclusive $Z/\gamma^* \to e^+e^-$ to be:

$$\text{Acceptance}(Z/\gamma^* \to e^+e^- + \text{X}) = 21.4\% \pm 0.1\% \tag{7.8}$$

Since the numerator in the acceptance calculation involves two reconstructed electrons, we apply a corrective weight to the numerator. Based on the p_T and Φ values of the two electrons, we estimate their reconstruction efficiencies (98% on average). The product of the inverse of those reconstruction efficiencies yields the corrective weight. We also apply the Z p_T correction factor (see Chapter 6.4.2) as an additional weight in both numerator and denominator of the acceptance.

7.2 Cross Section Calculation

After applying all corrections we estimate the number of corrected signal events from the diem invariant mass distribution (Figure 56). We fit a convolution of a Gaussian and Breit-Wigner shape to the Z peak and an exponential shape to describe the QCD and Drell-Yan contributions. We justify the choice of using an exponential shape for the QCD background

by looking at the diem invariant mass distribution of EM object pairs that were selected by applying "anti-electron cuts":

- All criteria that are applied to loose electron candidates as described in Section 6.3.2 except for the H-Matrix cut.

- H-Matrix(7) > 35

- Two of these objects per event.

In this way we select two jets with high electromagnetic energy content in the shower.

Since the Drell-Yan component is part of our signal, we need to disentangle the QCD component from the Drell-Yan component. Using the inclusive $Z/\gamma^* \to e^+e^-$ PYTHIA MC sample, we determine the percentage of Drell-Yan events in $Z/\gamma^* \to e^+e^-$ decays by fitting a Gaussian and Breit-Wigner shape to the Z component and an exponential shape to the Drell-Yan component. We find that 2.06% of the events in the inclusive $Z/\gamma^* \to e^+e^-$ sample are due to Drell-Yan.

Based on these fits we extract the number of signal events from direct Z Boson and Drell-Yan decays as well as the number of QCD background events in the diem invariant mass signal window (75 GeV $< M_{ee} <$ 105 GeV) [1]:

- Number of corrected signal events from Z Boson and Drell-Yan decays = 18,263.8

- Number of corrected QCD background events = 407.5

---

[1] The number of signal events is derived by counting all entries for a particular M_{ee} bin and subtracting from it the number of entries from the background fit.

Based on the integrated luminosity (343 pb^{-1}) and the acceptance (21.4%), we calculate the inclusive Z/γ^* production cross section times branching fraction into electrons:

$$\sigma \times \mathrm{BR}(Z/\gamma^* \to e^+e^-) = \frac{N-B}{\mathcal{L} \times A} = 248.9 \ \pm 2.5(\mathrm{stat}) \ \mathrm{pb} \qquad (7.9)$$

In order to check the procedure that leads to the cross section measurement, we perform a MC closure test. We evaluate the number of signal events, acceptance, and luminosity in MC. This leads to a calculated MC cross section (179 pb) that we compare to the input cross section that was used to generate the MC sample (183 pb). We find the calculated MC cross section to be in good agreement with the MC input cross section.

7.3   Comparisons to other measurements

Using the inclusive PYTHIA MC sample, we derive correction factors which allow us to estimate the Z/γ^* inclusive cross section for different diem invariant mass windows [1]. To calculate the correction factors, we count the number of Z/γ^* candidates at the particle level within different diem invariant mass ranges. We then take the ratio which yields the correction that is needed to account for the change in the diem invariant mass range.

Using the cross section ratio between the inclusive Z/γ^* cross section and the inclusive Z cross section in MC, we derive another correction factor which allows us to convert the measured inclusive Z/γ^* cross section into the inclusive Z cross section (66).

---

[1]The MC sample used a generator cut of $|\eta_Z| <4.2$. Although no restriction in η_Z would have been preferable, we believe that it has a negligible impact on the final results.
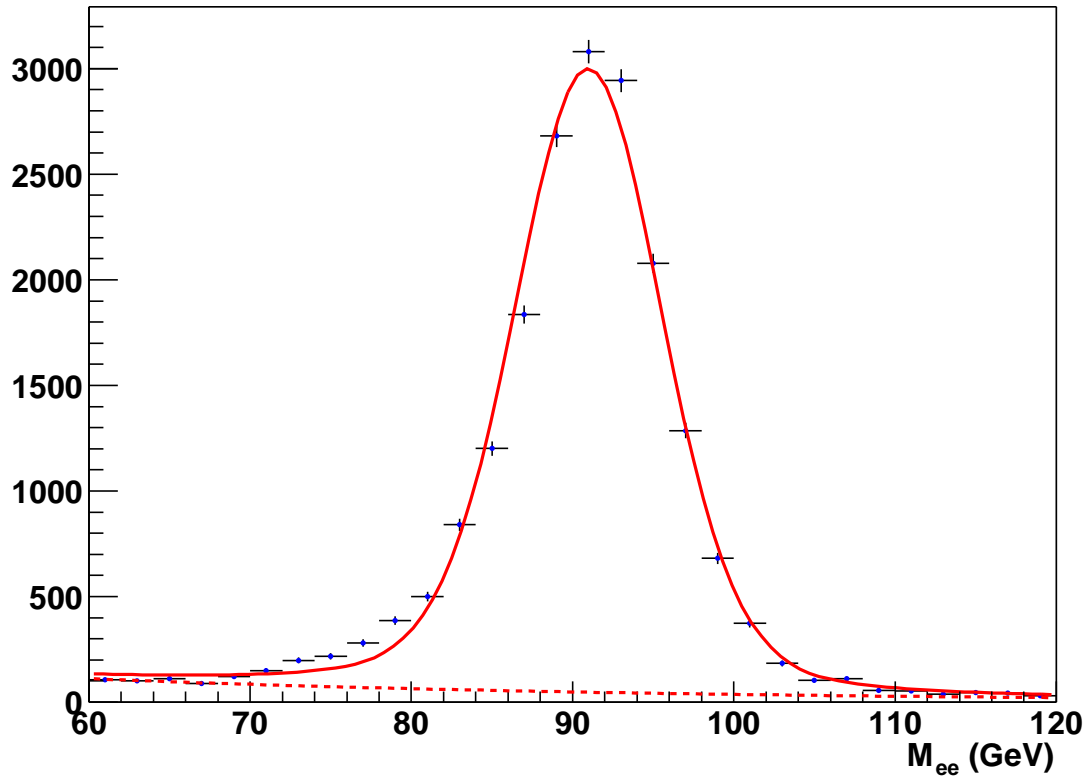

Figure 56. Diem invariant mass distribution for $Z/\gamma^* \to e^+e^- + X$ (Mean = 91.02 GeV $\pm$ 0.04 GeV, Width 4.03 GeV $\pm$ 0.04 GeV).

Process	Mass Range	Conversion
(a) Z/γ^*	75 GeV $< M_{ee} <$ 105 GeV	248.9 pb
(b) Z/γ^*	66 GeV $< M_{ee} <$ 116 GeV	248.9 pb $\cdot \frac{392,174}{379,255} = 257.4$ pb
(c) Z/γ^*	60 GeV $< M_{ee} <$ 130 GeV	248.9 pb $\cdot \frac{400,000}{379,255} = 262.5$ pb
(d) Z	60 GeV $< M_{ee} <$ 130 GeV	248.9 pb $\cdot \frac{1.852}{1.869 \cdot 0.948} = 260.2$ pb

TABLE VI

CROSS SECTION RESULTS FOR DIFFERENT DIEM INVARIANT MASS RANGES AND PROCESSES.

Table VI lists our inclusive Z/γ^* cross sections for different mass ranges, as well as the conversion into the inclusive cross section for pure Z boson exchange. We compare result (b) with the CDF measurement (67) for the inclusive Z/γ^* cross section (66 GeV $< M_{ee} <$ 116 GeV) of 255.8 ± 3.9(stat) pb.

CHAPTER 8

MEASUREMENT OF THE $\mathbf{Z}/\gamma^*(\to \mathbf{e^+e^-})+ \geq \mathbf{n}$ JET CROSS SECTIONS

In this section we outline the procedure to measure the $Z/\gamma^*(\to e^+e^-)$ production cross section for different inclusive jet multiplicities. For each jet multiplicity we determine the number of signal events from the diem invariant mass histograms. All efficiencies are examined for jet multiplicity dependence and applied to the diem invariant mass distributions as corrections (acceptance corrections are applied separately). We take into account jet reconstruction inefficiencies, as well as jet acceptance losses due to the electron-jet-overlap cut. The final cross sections are quoted for particle level jets (as opposed to calorimeter jets). We describe the *unsmearing* procedure that is used to convert calorimeter level jet multiplicities to particle level jet multiplicities. This is done in order to obtain final cross sections that are independent from detector resolution effects.

8.1   Efficiencies vs Jet Multiplicity

In the following sections we use the PYTHIA MC sample to derive corrections for the inclusive sample, and ALPGEN MC samples for the n-jet corrections.

8.1.1   Trigger Efficiency

We do not observe significant variations in the trigger efficiencies as jet activity increases (Figure 57). Therefore the same trigger corrections as for the inclusive sample are applied (see Chapter 7.1.1). Table VII summarizes electron trigger efficiencies for the pre-v12 and v12
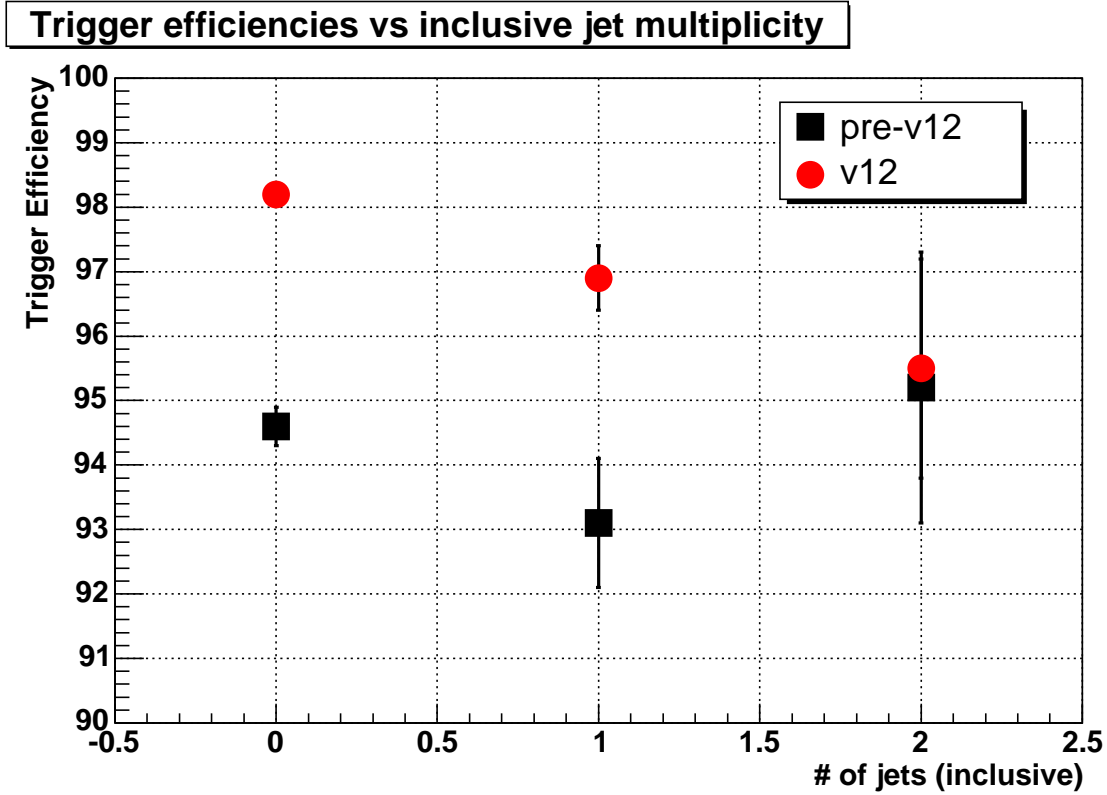

Figure 57. Average object based trigger efficiencies in data versus inclusive jet multiplicity.

datasets for different inclusive jet multiplicities. We assign an additional systematic error of ±5% for all jet multiplicities.

8.1.2 EM Reconstruction and Identification Efficiency

We apply the same EM corrections as for the inclusive sample to each jet multiplicity sample (see Chapter 7.1.2). In addition we estimate residual inefficiencies due to additional jet activity by looking at the distribution of average electron EM reco and ID efficiencies versus

Jet multiplicity	pre-v12	v12
≥ 0	$94.6\% \pm 0.3\% \pm 5.0\%$	$98.2\% \pm 0.1\% \pm 5.0\%$
≥ 1	$93.1\% \pm 1.0\% \pm 5.0\%$	$96.9\% \pm 0.5\% \pm 5.0\%$
≥ 2	$95.2\% \pm 2.1\% \pm 5.0\%$	$95.5\% \pm 1.7\% \pm 5.0\%$

TABLE VII

OBJECT BASED TRIGGER EFFICIENCIES WITH STATISTICAL AND SYSTEMATIC
ERRORS (RESPECTIVELY) FOR THE PRE-V12 AND V12 DATASETS FOR
DIFFERENT INCLUSIVE JET MULTIPLICITIES.

jet multiplicity (Figure 58). The averaged efficiencies are derived using the procedure outlined
in Chapter 7.1.2 for data and MC samples of different jet multiplicities.

Table VIII summarizes the electron EM reco and ID efficiencies in data and MC for different
jet multiplicities. No significant change of the average efficiencies with respect to jet multiplicity
is observed in data. Therefore no additional correction is applied. Due to the variation of the
various efficiencies a systematic error of $\pm 3\%$ is assigned for all jet multiplicities.

Based on the efficiency drop in MC we apply a factor of 1.02^2 as a corrective weight to each
event. This value is derived by taking the ratio of the EM efficiency for the inclusive sample
and the average of the EM efficiencies for the 1-jet, 2-jet and 3-jet samples.

8.1.3 EM-Track Match Efficiency

Figure 59 and Table IX show the average object based tracking efficiencies for different
jet multiplicities. In MC we use the value from the inclusive sample to correct for tracking
inefficiencies for all jet multiplicities. In data we use the inclusive value for the inclusive sample,
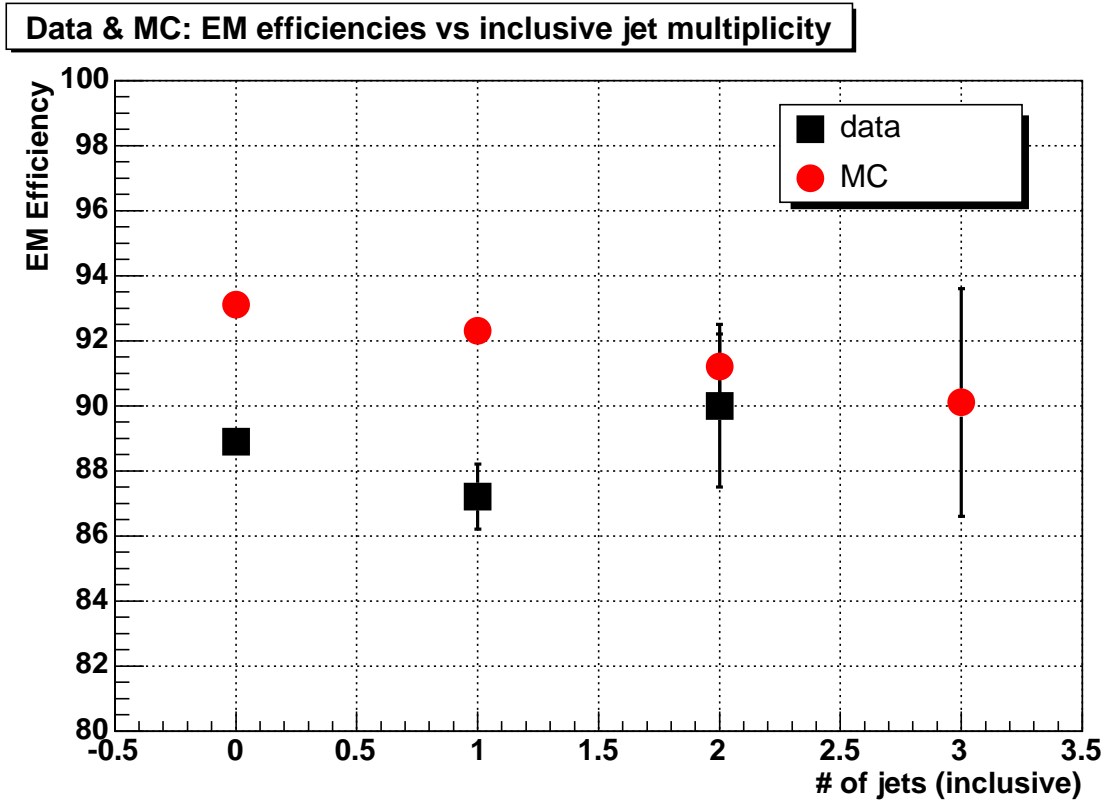

Figure 58. Average object based EM reco and ID efficiencies in data and MC versus inclusive jet multiplicity. There was not enough statistics available to estimate the EM efficiency in data for ≥ 3 jets.

Jet multiplicity	data	MC
≥ 0	$88.9\% \pm 0.3\% \pm 3.0\%$	$93.1\% \pm 0.1\%$
≥ 1	$87.2\% \pm 1.0\% \pm 3.0\%$	$92.3\% \pm 0.3\%$
≥ 2	$90.0\% \pm 2.5\% \pm 3.0\%$	$91.2\% \pm 1.0\%$
≥ 3	(n/a)	$90.1\% \pm 3.5\%$

AND MC FOR DIFFERENT INCLUSIVE JET MULTIPLICITIES.

the 1-jet value for the 1-jet sample and the 2-jet value for all other jet samples.

Table X lists the systematic errors for the data efficiencies. For the 1-jet and 2-jet samples,
we use the respective statistical errors as systematics. For the 3-jet, 4-jet and 5-jet samples,
we add the 2-jet statistical error in quadrature with the difference between a linear fit to the
available data points and the 2-jet efficiency value.
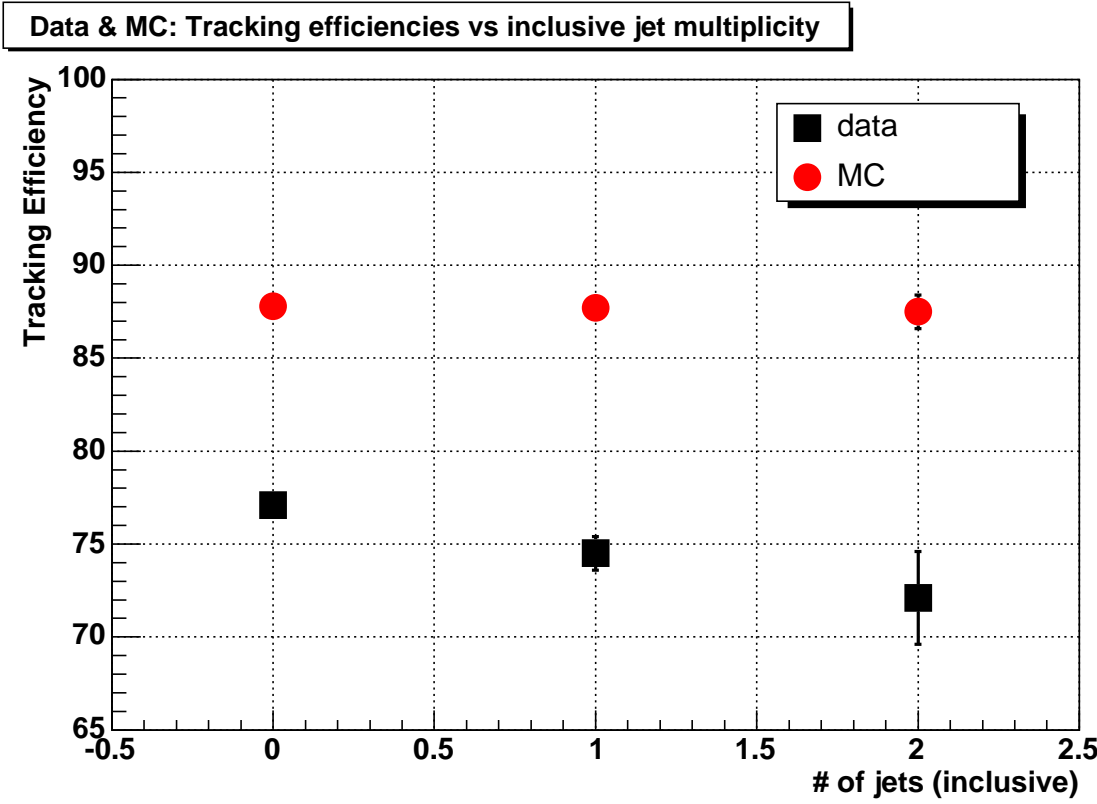

Figure 59. Average object based tracking efficiencies in data and MC versus inclusive jet multiplicity.

Jet multiplicity	Data Efficiency	Systematic Uncertainty
≥ 0	77.1%	$\pm 0.3\%$
≥ 1	74.5%	$\pm 0.9\%$
≥ 2	72.1%	$\pm 2.5\%$
≥ 3	72.1%	$\pm 3.5\%$
≥ 4	72.1%	$\pm 5.6\%$
≥ 5	72.1%	$\pm 7.9\%$

TABLE X

OBJECT BASED TRACKING EFFICIENCIES WITH SYSTEMATIC ERRORS.

8.1.4 Acceptance

We use the ALPGEN MC samples to estimate the acceptances for different jet multiplicities[1]. The numerator for the n-jet acceptance contains the number of events satisfying the following requirements:

- Primary vertex cut: $|PVZ| < 60$ cm

- Electron cuts: $p_T > 25$ GeV and $|\eta| < 1.1$

- Diem invariant mass cut: 75 GeV $< M_{ee} < 105$ GeV

- Particle level jet cut: n jets with $p_T > 20$ GeV and $|\eta| < 2.5$

The denominator for the n-jet acceptance contains the number of events satisfying the following requirements:

---

[1]The $Z+3$ jet sample is used for jet multiplicities of 3, 4, and 5.

Jet multiplicity	Acceptance
≥ 0	$21.4\% \pm 0.1\%$
≥ 1	$25.1\% \pm 0.2\%$
≥ 2	$25.4\% \pm 0.2\%$
≥ 3	$27.4\% \pm 0.3\%$
≥ 4	$28.5\% \pm 0.7\%$
≥ 5	$30.3\% \pm 1.9\%$

TABLE XI

ACCEPTANCES WITH STATISTICAL ERRORS FOR DIFFERENT JET MULTIPLICITIES.

- MC generator diem invariant mass cut: 75 GeV $< M_{ee} <$ 105 GeV

- Particle level jet cut: n jets with $p_T >$ 20 GeV and $|\eta| < 2.5$

No additional Z p_T correction is needed since the Z p_T distributions between data and ALPGEN MC agree well (see Chapter 6.4.2). Table XI summarizes the acceptances for different jet multiplicities. On average, higher jet multiplicities lead to higher Z p_T, since the Z boson recoils against the jet(s) in the event. This in turn leads to electrons coming from Z decays that are more likely to pass the acceptance requirements. Therefore, as jet multiplicities increase, acceptances increase as well.

8.1.5   Jet Reconstruction and Identification Efficiency

To estimate the jet reco/ID efficiency in data we use the "Z p_T balance" method to measure the scaling factor needed to adjust the MC jet reco/ID efficiency to data, and then use MC to measure the "straight" reco/ID jet efficiency with respect to the particle level jets (68). The

Z p_T balance method relies on the recoil of a jet against the Z boson. We select events with Z candidates and search for a recoiling calorimeter jet opposite in Φ. We measure the "efficiency" of finding a recoiling jet as a function of the Z p_T in data and MC. The ratio of these efficiencies in data and MC gives us the scaling factor that we apply to the MC in order to make it agree with the data jet reco/ID efficiency. We then measure the straight jet reco/ID efficiency in MC by matching particle level jets with calorimeter jets within a search cone of $\Delta R = 0.4$. The jet reco/ID efficiency is plotted versus MC particle jet p_T. The p_T values of the particle jets are smeared with the data energy resolutions (see Chapter 6.2.1). Figure 60 shows the data jet reconstruction efficiencies for different regions in the calorimeter.
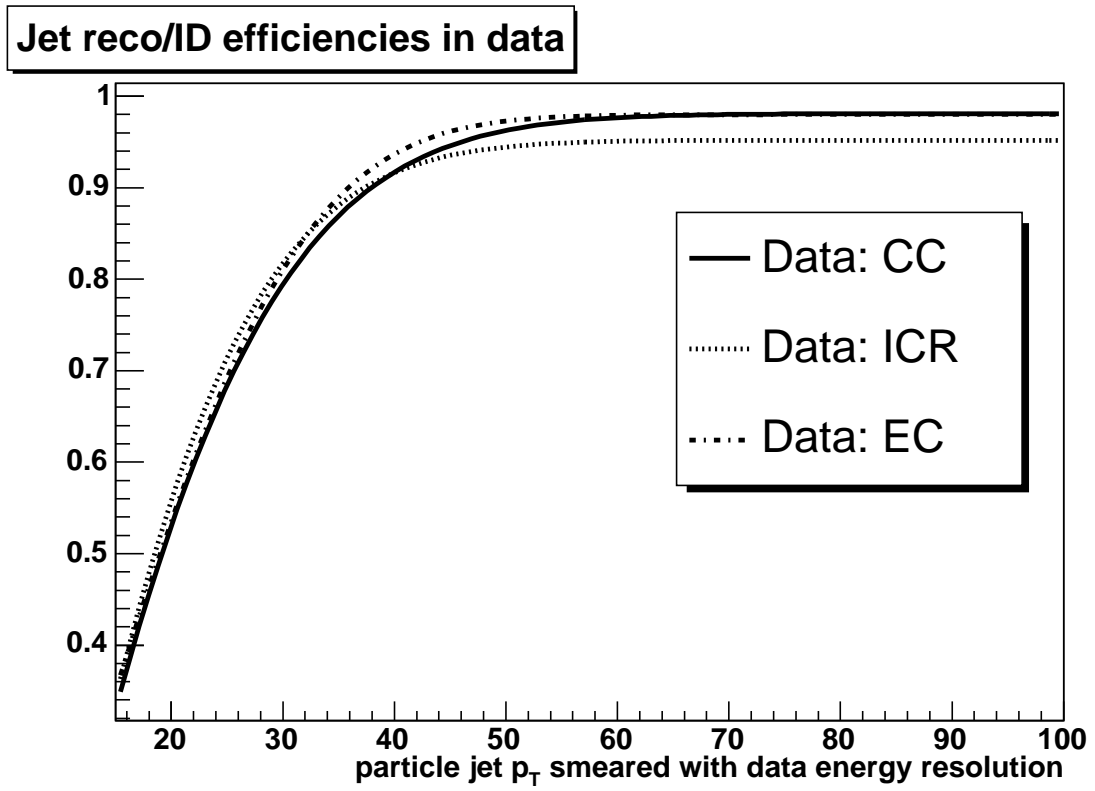

Figure 60. Jet reco/ID efficiencies in data. CC $= -0.7 < |\eta_{det}| < 0.7$, ICR $= 0.7 < |\eta_{det}| < 1.5$, EC $= 1.5 < |\eta_{det}| < 2.5$.

8.2   Cross Section Calculation

8.2.1   Unsmearing

In order to determine particle level cross sections, we unsmear the measured data jet multiplicities from detector resolution effects. We use a special $Z{+}1$ jet PYTHIA MC sample by choosing PYTHIA 2-to-2 subprocesses 15 and 30 [1] with a parton p_T cut-off of 8 GeV and by applying vertex smearing. This sample only contains particle level jets (no detector simulation). We then apply the full data resolution smearing to the particle jet p_T as well as the data jet reco/ID efficiencies. Comparing the inclusive jet multiplicity for this MC sample with the one in data gives an idea of how well the MC describes the data (Figure 61). There is increasing disagreement at higher jet multiplicities, since PYTHIA does not include higher order contributions at the hard scatter level. We correct for this discrepancy by taking the ratio between data and MC for each inclusive jet multiplicity (Figure 62) and then applying correction factors (per event) based on the absolute values of these ratios. After this additional step we again compare the inclusive jet multiplicity spectrum in MC with the one in data and find much better agreement (Figure 63). We use this corrected MC sample to derive the coefficients that unsmear the measured data jet multiplicities, also taking into account jet reco/ID inefficiencies. Figure 64 - Figure 75 compare jet p_T and η distributions between the data and MC sample.

To calculate the coefficients we first take the inclusive jet multiplicity histogram for particle level jets with $p_T > 20$ GeV and $|\eta_{physics}| < 2.5$ and divide it by the inclusive jet multiplicity

---

[1] $f_i \bar{f}_i \to g Z^0$ and $f_i g \to f_i Z^0$
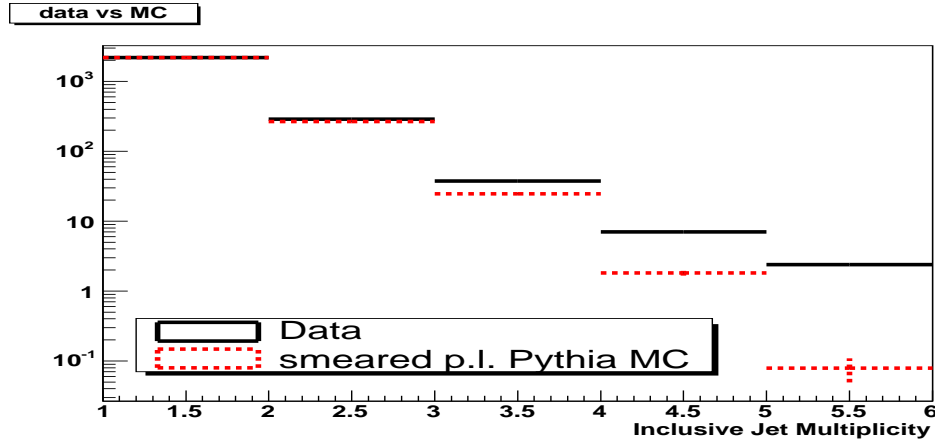

Figure 61. Comparing inclusive jet multiplicities between data and particle level MC (applying data resolution smearing and data jet reco/ID efficiencies). The distributions are normalized with respect to the first bin.

histogram for particle level jets with smeared $p_T > 20$ GeV and $|\eta_{physics}| < 2.5$ (after applying jet reco/ID efficiencies). The exact values of these ratios yield the unsmearing and jet reco/ID coefficients which can be applied as multiplicative factors to the measured jet multiplicities in data. Figure 76 shows the numerator and denominator jet multiplicity histograms, as well as the ratio when applying jet smearing and jet reco/ID efficiencies in the denominator. For comparison Figure 77 shows the same distributions without applying jet reco/ID efficiencies, i.e. applying only jet smearing.

We use the statistical error of each unsmearing and jet reco/ID coefficient as a statistical error to the final cross sections (see Chapter 9.7). Table XII summarizes all coefficients.

UNCERTAINTY DUE TO RESOLUTION AND JET RECO/ID EFFICIENCY.

8.2.2 <u>Electron-Jet-Overlap Correction</u>

Using the tag-and-probe method outlined in Chapter 7.1.2, we plot the ΔR distribution between probe tracks and reconstructed jets that pass all jet quality cuts except for the electron-jet-overlap cut in data and MC (Figure 78 and Figure 79).

We see an excess of entries at ΔR values of 0 and π due to fake jets (i.e. originated from the electron energy deposits) which survived the jet quality cuts. Therefore we reject all jets that are near either of the two electrons within $\Delta R = 0.4$. Figure 80 shows the same distribution as in Figure 78 after adding the electron-jet-overlap cut. For comparison Figure 81 shows the ΔR between generated electrons and partons in data and MC.

An additional correction needs to be derived in order to account for the real jets that are removed by the electron-jet-overlap cut. Using the same MC sample as for the unsmearing studies (see Chapter 8.2.1), we estimate the correction factors due to the electron-jet-overlap by taking the ratio of the inclusive parton multiplicity distribution for all partons with $p_T > 20$ GeV and $|\eta| < 2.5$ and the inclusive parton multiplicity distribution for partons that are outside of the ΔR cone with respect to the electrons from the Z.

We derive correction factors using ΔR cones of size 0.4 and 0.7 and take the middle value as the final correction factors. This is done in order to account for the position resolution between partons and calorimeter jets (see Figure 82). Additionally we apply a linear fit to the final values in order to compensate for statistical fluctuations.

Table XIII summarizes the electron-jet-overlap correction factors for different jet multiplicity

APPLYING THE UNSMEARING, JET RECO/ID AND ELECTRON-JET-OVERLAP
CORRECTIONS).

8.2.3 Cross Sections

Figure 83 - Figure 87, shows the diem invariant mass distributions for jet multiplicities ≥ 1
to ≥ 5 which we use to extract the number of signal and background events for the cross section
calculation (corrected for trigger, EM and tracking inefficiencies). For jet multiplicities of ≥ 1
and ≥ 2, we follow the same technique as outlined in Chapter 7.2. For jet multiplicities of ≥ 3
we use sidebands to estimate the background. For higher jet multiplicities there is not enough
statistics to estimate any background.

Table XIV summarizes the number of signal and background events for each jet multiplicity.
The fully corrected and unsmeared cross sections versus jet multiplicities (with jet $p_T > 20$ GeV,
$|\eta| < 2.5$) are shown in Figure 88 with statistical errors.

CHAPTER 9

SYSTEMATICS

This chapter evaluates various sources for systematic errors.

9.1   Jet Energy Scale Systematic Error

We estimate the error due to the jet energy scale (version 5.3) by varying the energy scale correction up and down by 1σ (combined systematic and statistical JES uncertainty) and subsequently recalculating the diem invariant mass histograms (corrected for trigger, EM reco/ID, and EM-Track matching inefficiencies) to get the number of corrected signal events for different jet multiplicities. We then recalculate the cross sections to estimate the JES error. Figure 89 shows the effect of the JES error on the corrected jet multiplicity distribution.

We fit the percentage errors for each jet multiplicity linearly to get a smooth curve and to be independent from statistical fluctuations. The final JES error is the maximum of the actual data error and the fit error. Table XV summarizes the JES errors. The JES errors are the dominant errors in this analysis.

9.2   Systematic Error of Cross Section Unfolding

A detailed description of the jet reco/ID efficiency errors can be found in Reference (68). Figure 90, Figure 91 and Figure 92 show the jet reco/ID efficiencies with error bands for central, ICR, and forward rapidities. The errors are due to the statistical uncertainty of the scale factor and straight efficiency, the missing E_T cut, and the differences between CKKW and PYTHIA
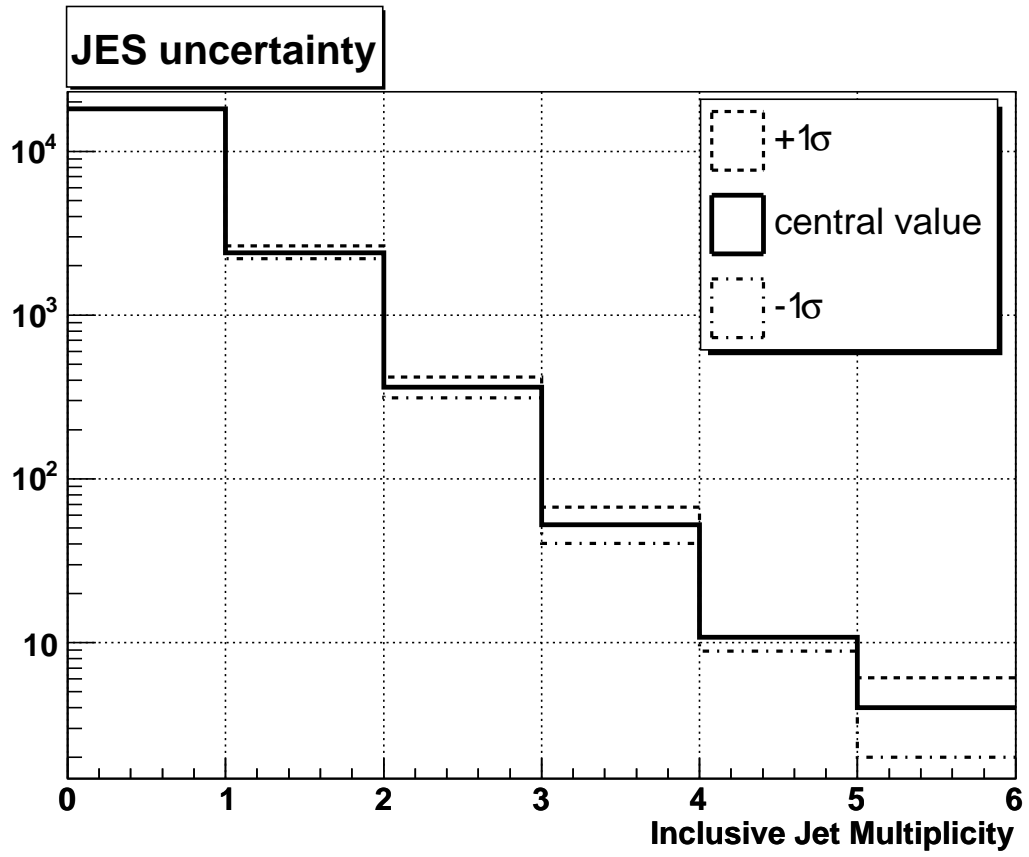

Figure 89. $\pm 1\sigma$ fluctuation of the jet energy scale (JES 5.3)

Jet multiplicity	Cross Section	JES Errors
≥ 1	29.6 pb	± 2.9 pb
≥ 2	4.50 pb	± 0.83 pb
≥ 3	0.655 pb	± 0.185 pb
≥ 4	0.151 pb	± 0.057 pb
≥ 5	0.1035 pb	± 0.0520 pb

TABLE XV

FINAL CROSS SECTIONS WITH JET ENERGY SCALE ERRORS.

MC generators. To estimate the jet reco/ID uncertainty, we rederive the unsmearing and jet reco/ID correction factors using the upper and lower error bands of the jet reco/ID efficiencies.

Figure 93 shows the scale factor used in this analysis overlaid with the average scale factor determined by the Top group. Both curves agree within the error bands.

As a cross check we perform a closure test where we compare the "efficiency" of finding a recoiling jet as a function of Z p_T in data and particle level MC (Figure 94). Both the data and MC distributions have a jet p_T cut of 8 GeV applied. In addition, the MC particle jets are smeared with the data jet energy resolution. We also apply the data jet reco/ID efficiencies (by dropping jets) to the MC sample. We find good agreement between the two distributions within errors. Table XVI summarizes the jet reco/ID errors.

The parameterization of the jet resolution is based on JES 5.0 with T42 applied (see Chapter 6.2.1). We need to account for the difference between the JES 5.0 and 5.3 parameterizations. It has been shown (see Figure 95) that there is a change of approximately 5% between JES 5.1

Jet multiplicity	Cross Section	Jet Reco/ID Errors
≥ 1	29.6 pb	$^{+2.2}_{-1.6}$pb
≥ 2	4.50 pb	$^{+0.64}_{-0.57}$pb

≥ 4	0.157 pb	$^{+0.041}_{-0.028}$pb
≥ 5	0.1035 pb	$^{+0.0567}_{-0.0287}$pb

TABLE XVI

FINAL CROSS SECTIONS WITH JET RECO/ID ERRORS.

and 5.3 (69). A conservative error of 10% is therefore assigned to account for the jet resolution uncertainty.

We estimate the error due to the jet resolution smearing in the unsmearing procedure (Chapter 8.2.1) by varying the data jet resolution by $\pm$ 10%. Table XVII summarizes the jet resolution errors.

9.3   Electron-Jet-Overlap Systematic Error

For each jet multiplicity we derive electron-jet-overlap correction factors using ΔR=0.4 and ΔR=0.7 rejection cones and then use the middle value as the final correction. The systematic error is the difference between the middle values and the correction factors derived with ΔR=0.4 and ΔR=0.7. Additionally we apply a linear fit to the final errors in order to compensate for statistical fluctuations.

Table XVIII summarizes the systematic errors for the electron-jet-overlap cut.

≥ 5	0.1035 pb	± 0.0067 pb

TABLE XIX

FINAL CROSS SECTIONS WITH LUMINOSITY ERRORS.

9.4 Luminosity Systematic Error

The error due to the uncertainty in the luminosity measurement is 6.5% (17). Table XIX summarizes the luminosity errors.

9.5 Systematic Errors Due to Efficiencies

In the following we take the systematic uncertainties of the object based efficiencies from Chapters 8.1.1 to 8.1.3, convert them into event based systematic uncertainties, and then propagate those uncertainties to the cross sections.

9.5.1 Trigger Efficiency

We estimate a relative systematic error of $\pm 1\%$ due to the variations in the trigger efficiencies versus jet multiplicity (see Chapter 8.1.1):

$$\varepsilon_{Object}(\text{pre-v12, inclusive sample}) = 94.6\%, \quad \delta\varepsilon_{Object} = 5\% \tag{9.1}$$

$$\varepsilon_{Event} = 2 \cdot \varepsilon_{Object} - \varepsilon_{Object}^2 = 99.7\% \tag{9.2}$$

$$\varepsilon_{Event}(-1\sigma) = 2 \cdot (\varepsilon_{Object} - \delta\varepsilon_{Object}) - (\varepsilon_{Object} - \delta\varepsilon_{Object})^2 = 98.9\% \tag{9.3}$$

$$\text{Relative Error} = \frac{99.7\% - 98.9\%}{99.7\%} = 0.8\% \approx 1\% \tag{9.4}$$

9.5.2 EM Reconstruction and Identification Efficiency

We estimate a relative systematic error of $\pm 7\%$ due to the variations in the EM reco and ID efficiencies versus jet multiplicity (see Chapter 8.1.2):

$$\varepsilon_{Object}(\text{data, inclusive sample}) = 88.9\%, \quad \delta\varepsilon_{Object} = 3\% \tag{9.5}$$

$$\varepsilon_{Event} = \varepsilon_{Object}^2 = 79.0\% \tag{9.6}$$

$$\varepsilon_{Event}(-1\sigma) = (\varepsilon_{Object} - \delta\varepsilon_{Object})^2 = 73.8\% \tag{9.7}$$

$$\text{Relative Error} = \frac{79.0\% - 73.8\%}{79.0\%} = 6.6\% \approx 7\% \tag{9.8}$$

9.5.3 EM-Track Match Efficiency

Table XX summarizes the relative systematic uncertainties due to the variations in the EM-Track matching efficiencies versus jet multiplicity (see Chapter 8.1.3). We estimate the uncertainties based on the following equations:

$$\varepsilon_{Object}(\text{data, n-jet sample}) = \varepsilon_n, \quad \delta\varepsilon_{Object}(\text{data, n-jet sample}) = \delta\varepsilon_n \tag{9.9}$$

Jet Multiplicity	Relative Error
≥ 1	0.5%
≥ 2	1.5%
≥ 3	2.3%
≥ 4	3.7%
≥ 5	5.5%

TABLE XX

RELATIVE ERRORS DUE TO UNCERTAINTY IN EM-TRACK MATCHING EFFICIENCIES.

$$\varepsilon_{Event} = 2 \cdot \varepsilon_n - \varepsilon_n^2 \tag{9.10}$$

$$\varepsilon_{Event}(-1\sigma) = 2 \cdot (\varepsilon_n - \delta\varepsilon_n) - (\varepsilon_n - \delta\varepsilon_n)^2 \tag{9.11}$$

$$\text{Relative Error} = \frac{\varepsilon_{Event} - \varepsilon_{Event}(-1\sigma)}{\varepsilon_{Event}} \tag{9.12}$$

9.5.4 Overall Efficiency Systematic Error

Table XXI summarizes the overall systematic error due to the efficiencies after adding all contributions in quadrature.

9.6 Jet Promotion Systematic Error

We study the effect of additional jets from multiple interactions within the same beam crossing, i.e. *jet promotion*. We compare jet multiplicities of events that have exactly one reconstructed primary vertex with events that have at least two reconstructed primary vertices

Jet Multiplicity	Cross Section	Efficiency Errors
≥ 1	29.6 pb	± 2.1 pb
≥ 2	4.50 pb	± 0.32 pb
≥ 3	0.655 pb	± 0.047 pb
≥ 4	0.151 pb	± 0.011 pb
≥ 5	0.1035 pb	± 0.0093 pb

TABLE XXI

OVERALL SYSTEMATIC UNCERTAINTIES DUE TO EFFICIENCIES (TRIGGER, EM, TRACKING).

(Table XXII).

The two samples are normalized with respect to the number of events in the inclusive jet multiplicity bin. Initially the single vertex sample contains 7,848 events and the 2 (or more) vertex sample contains 5,900 events.

We conclude that the jet promotion effect is small since the discrepancy between the two samples is within the statistical error.

We also compare the average number of reconstructed primary vertices for different jet multiplicity samples (Table XXIII) and do not see an effect within statistical errors.

9.7 Statistical Uncertainty

The statistical uncertainty has the following contributions:

Jet multiplicity	Exactly one primary vertex	At least two primary vertices
≥ 0	5,900	5,900
≥ 1	705	696
≥ 2	92	97
≥ 3	11	16
≥ 4	3	1
≥ 5	1	1

TABLE XXII

NUMBER OF EVENTS FOR DIFFERENT INCLUSIVE JET MULTIPLICITIES WHEN
REQUIRING EXACTLY ONE RECONSTRUCTED PRIMARY VERTEX AND AT LEAST
TWO RECONSTRUCTED PRIMARY VERTICES. ENTRIES ARE NORMALIZED WITH
RESPECT TO THE 2 VERTEX SAMPLE.

Jet multiplicity	Average number of primary vertices
≥ 1	1.583 ± 0.852
≥ 2	1.622 ± 0.911
≥ 3	1.733 ± 0.814
≥ 4	1.4 ± 0.8
≥ 5	2.0 ± 1.0

TABLE XXIII

AVERAGE NUMBER OF RECONSTRUCTED PRIMARY VERTICES FOR DIFFERENT
JET MULTIPLICITIES.

- We estimate the error due to the total number of corrected events δN_{corr} (corrected for Trigger, EM and Tracking inefficiencies) with the following Equation:

$$\delta N_{corr} = \sqrt{(w_{average} \cdot \delta N_{uncorr})^2 + (N_{uncorr} \cdot \delta w_{average})^2} \qquad (9.13)$$

where N_{corr} is the total number of corrected events, N_{uncorr} is the total number of un-corrected events, and $w_{average}$ is the average weight used to correct for EM, Trigger and Tracking inefficiencies (≈ 1.36).

- We estimate the error due to the number of background events δB by fitting an exponential function $a \cdot \exp(\ b \cdot x\ )$ to the measured number of QCD events (Figure 96) and then using the error due to the two fitting parameters a and b as the uncertainty. The error of the exponential fit takes into account that the fitting parameters a and b are correlated:

$$f(x) = a \cdot exp(b \cdot x) \qquad (9.14)$$

$$\delta f(x) = \sqrt{\left(\frac{\partial f}{\partial a} \cdot \delta a\right)^2 + \left(\frac{\partial f}{\partial b} \cdot \delta b\right)^2 + 2 \cdot \frac{\partial f}{\partial a} \cdot \frac{\partial f}{\partial b} \cdot covariance(a,b)}. \qquad (9.15)$$

- We add an additional error due to the statistical uncertainty of the acceptances (see Table XI).

- We add the statistical uncertainty due to the unsmearing and jet reco/ID coefficients (see Chapter 8.2.1).

CROSS SECTIONS WITH STATISTICAL ERRORS.

Table XXIV summarizes the statistical errors.

CHAPTER 10

CONCLUSIONS

10.1 Final Results

We measure the $Z/\gamma^*(\to e^+ e^-) + \geq n$ jet cross sections for jet multiplicities of 0 to 5. The results are presented in terms of absolute cross sections and cross section ratios normalized with respect to the inclusive cross section.

Table XXV summarizes all measured cross sections, together with uncertainties due to statistics, systematics, and luminosity. Also listed is the number of fully corrected signal events for each jet multiplicity sample. Table XXVI and Figure 97 compare the measured cross sections with results from MCFM and CKKW MC simulations (see Chapter 6.2). The CKKW cross sections are normalized with respect to the measured cross section for the 1-jet sample. The matrix element generation of the CKKW samples was done up to jet multiplicities of 3. Higher jet multiplicities are due to parton showering and hadronization simulated with PYTHIA.

Table XXVII and Figure 98 compare the cross section ratios with results from MCFM and CKKW MC simulations. For cross section ratios (R_n), the luminosity measurement uncertainties cancel. All other systematic uncertainties contribute as shown in the following equation:

$$\delta R_n = \frac{\delta \sigma_n}{\sigma_0}, \quad \text{with} \quad \sigma_0 = 248.9 \ pb. \tag{10.1}$$

Jet Multiplicity	# of Signal Events	$Z/\gamma^*(\to e^+ e^-) + \geq n$ Jet Cross Section
≥ 0	18,263.8	248.9 pb ± 2.5(stat) ± 16.2(lumi)
≥ 1	2,550.7	29.6 pb ± 0.81(stat) $^{+4.3}_{-4.0}$(sys) ± 1.9(lumi)
≥ 2	391.9	4.50 pb ± 0.32(stat) $^{+1.1}_{-1.1}$(sys) ± 0.29(lumi)
≥ 3	63.6	0.655 pb ± 0.13(stat) $^{+0.22}_{-0.22}$(sys) ± 0.043(lumi)
≥ 4	15.3	0.151 pb ± 0.070(stat) $^{+0.072}_{-0.066}$(sys) ± 0.010(lumi)
≥ 5	6.8	0.104 pb ± 0.074(stat) $^{+0.10}_{-0.06}$(sys) ± 0.0067(lumi)

TABLE XXV

CROSS SECTIONS FOR DIFFERENT INCLUSIVE JET MULTIPLICITIES. NUMBER OF
SIGNAL EVENT ENTRIES HAVE UNSMEARING, JET RECO/ID AND
ELECTRON-JET-OVERLAP CORRECTIONS APPLIED.

We also compare jet p_T distributions for different jet multiplicities between data and ALP-GEN+PYTHIA MC simulations (Figure 99).

We find our results to be in good agreement with QCD predictions.

10.2   Future Plans

Future work on this analysis at DØ will include the use of CKKW samples with matrix element generation of up to 5 jets. This will further improve cross section comparisons at higher jet multiplicities, as well as unsmearing results.

Additional background processes also need to be evaluated. Preliminary studies indicate that contributions from backgrounds such as $Z/\gamma^* \to \tau^+ \tau^-$ are small.

Jet Multiplicity	Measured Cross Section	MCFM	CKKW
≥ 0	248.9 pb ± 16.4(tot)	241.5 pb ± 0.1(stat)	-
≥ 1	29.6 pb $^{+4.8}_{-4.6}$(tot)	26.2 pb ± 0.044(stat)	29.6 pb
≥ 2	4.50 pb $^{+1.2}_{-1.2}$(tot)	5.21 pb ± 0.069(stat)	5.22 pb
≥ 3	0.655 pb $^{+0.26}_{-0.26}$(tot)	-	0.798 pb
≥ 4	0.151 pb $^{+0.10}_{-0.10}$(tot)	-	0.096 pb
≥ 5	0.104 pb $^{+0.13}_{-0.10}$(tot)	-	0.008 pb

TABLE XXVI

COMPARISON OF MEASURED CROSS SECTIONS WITH RESULTS FROM MCFM AND CKKW.

Jet multiplicity	$\frac{\sigma(Z/\gamma^*(\to e^+e^-)+\geq nJets)}{\sigma_{Z/\gamma^*}}$ $[\cdot 10^{-3}]$	MCFM	CKKW
≥ 1	119.1 ± 3.3(stat) $^{+17.2}_{-16.2}$(sys)	108.4	119.1
≥ 2	18.1 ± 1.3(stat) $^{+4.5}_{-4.3}$(sys)	21.6	21.0
≥ 3	2.6 ± 0.52(stat) $^{+0.90}_{-0.89}$(sys)	-	3.2
≥ 4	0.61 ± 0.28(stat) $^{+0.29}_{-0.27}$(sys)	-	0.39
≥ 5	0.42 ± 0.30(stat) $^{+0.42}_{-0.24}$(sys)	-	0.03

TABLE XXVII

COMPARISON OF MEASURED CROSS SECTION RATIOS WITH RESULTS FROM MCFM AND CKKW.
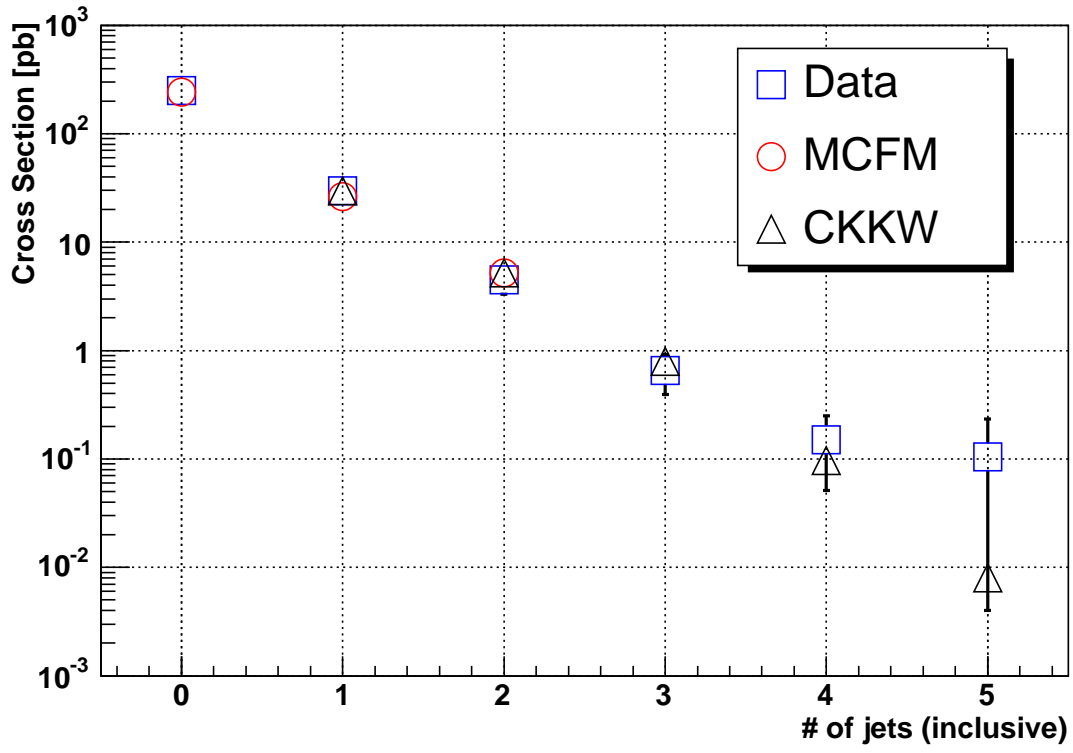

Figure 97. $Z/\gamma^*(\to e^+e^-)+ \geq n$ jet cross sections in data (with total errors) compared with MCFM and CKKW.
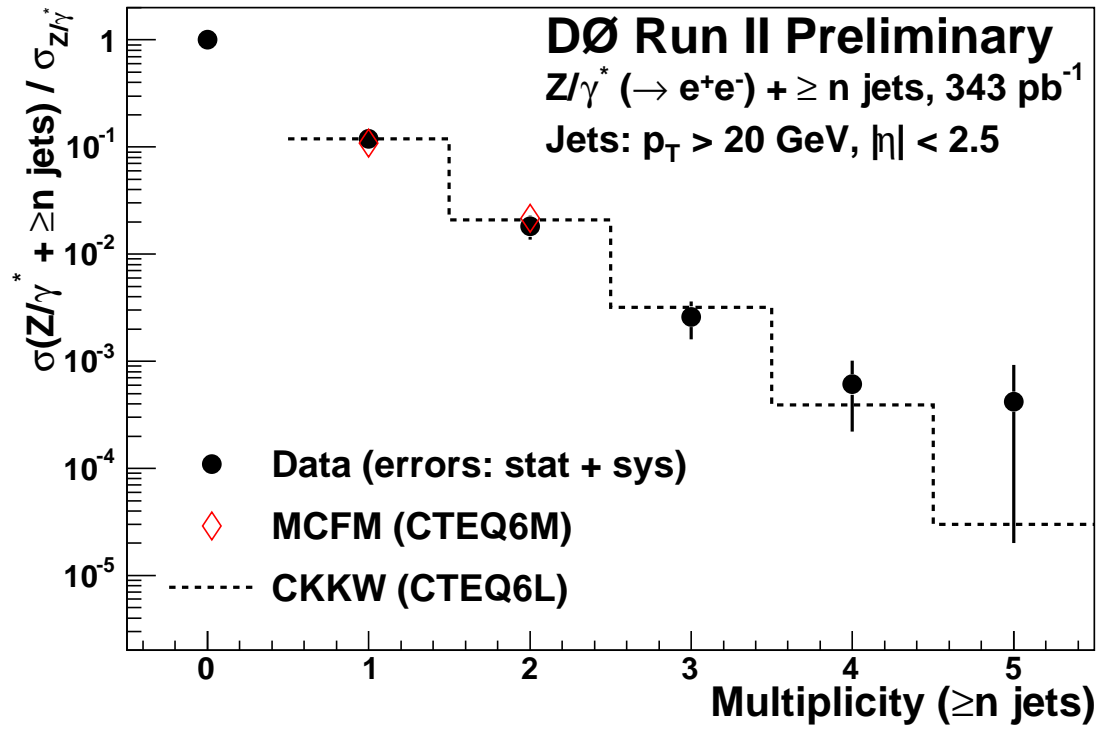

Figure 98. Ratios of the $Z/\gamma^*(\to e^+e^-)+ \geq n$ jet cross sections to the total inclusive $Z/\gamma^* \to e^+e^-$ cross section versus n. The errors on the data include the combined statistical and systematic uncertainties. The dashed line (CKKW) represents the predictions of LO matrix Element calculations using PYTHIA for parton showering and hadronization, normalized to the measured $Z/\gamma^*+ \geq 1$ jet cross section ratio. The diamonds represent the MCFM predictions.
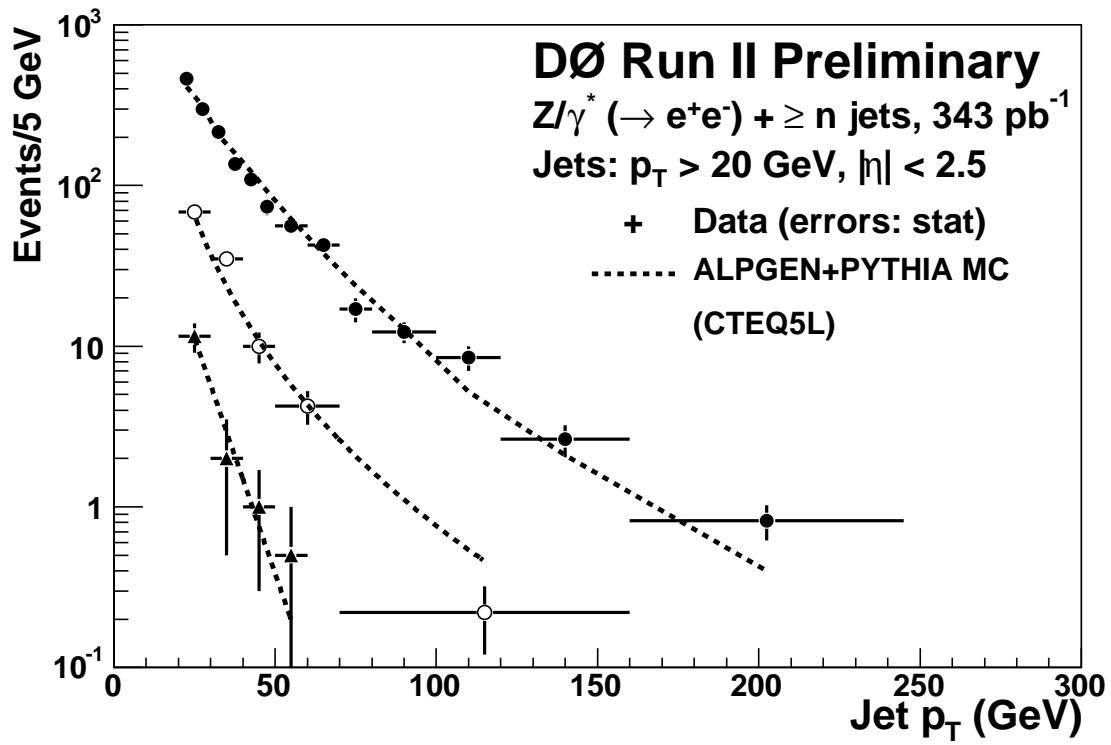

Figure 99. Data to theory (ALPGEN+PYTHIA) comparison for the highest p_T jet distribution in the $Z+ \geq 1$ jet sample, for the second highest p_T jet distribution in the $Z+ \geq 2$ jet sample and for the third highest p_T jet distribution in the $Z+ \geq 3$ jet sample. The errors on the data are only statistical.

Appendix B

THE LEVEL 2 TRIGGER SYSTEM AND ALPHA BOARDS

Level 2 is an essential part of the DØ trigger and data acquisition system (70; 71; 72; 73). It was designed to provide a reduction in the event rate by a factor of 10 within a 100 μsec time window while inducing less than 5% deadtime. As outlined in Chapter 3.4.2 the L2 trigger system is organized as a two-stage *stochastic pipeline*. In the first step (*preprocessing stage*) sub-detector based proto-objects are formed by preprocessors. The second step (*global processing*) combines the information provided by the preprocessors to make the event-wide L2 trigger decision. One advantage of this design is that each preprocessor is able to operate in parallel, independently from all other preprocessors. This avoids deadtime since decision times can vary significantly from event to event. Additionally up to 16 events can be queued in buffers (*FIFOs*) between the stages. Figure 100 illustrates the relation between sub-detectors, and L1/L2 trigger elements.

B.1   The Standard Level 2 Crate

All L2 systems occupy 9U[1] VME crates (74):

- Forward Muon Preprocessor (L2MUF)

- Central Muon Preprocessor (L2MUC)

---

[1]1U = 1.75 in

Figure 100. Schematic view of subdetectors with L1 and L2 trigger elements. Horizontal arrows indicate the direction of dataflow.

- Calorimeter Preprocessor (L2CAL)

- Preshower Preprocessor (L2PS)

- Tracking Preprocessor (L2CTT/L2STT)

- Global Processor (L2GBL)

Each crate contains a 64-bit VME bus (75) and a custom-built high-speed bus (*Magic Bus*, or MBus) for data-handling on an auxiliary backplane (76). The 128 bit MBus supports data rates of up to 320 Mbit/s. Figure 101 shows a schematic view of the L2CAL crate with its main components:

MPM (*Multi Port Memory*): A Bit3 MPM card is used as the VME crate controller. It downloads run-time parameters and reports monitoring data to the Trigger Control Computer (TCC[1]).

VBD (*VME Buffer Driver*): A VBD card is used to write data to the L3 system. The VBD cards were later replaced by VME single board computers (SBC).

Workers/Administrator (*Alpha Boards*): The Alpha Boards perform the main processing step within the L2 trigger system. Their main purpose is the application of the L2 trigger algorithms (*Worker*). They also handle additional event processing and local trigger control tasks (*Administrator*). A detailed overview of the Alpha Board system architecture is given in Chapter B.2. The Alpha Boards were later substituted by *Beta Boards* (77).

---

[1]TCC handles run control, downloads run-specific information, and collects monitoring data.

MBT (*Magic Bus Transceiver*): The MBT cards (78) receive L1 information and broadcast it to the Worker/Administrator via the MBus. After preprocessing is finished, the outputs are sent to the L2 Global Processor (L2GBL). The MBT cards also receive information regarding L1 trigger accepts, L2 trigger decisions, and system-wide initializations (*Serial Command Link Initialize*, or SCLinit). Depending on the processing load, additional *Assistant MBTs* can be added to the *Pilot MBT*.

Specialized hardware: In some cases additional specialized hardware for data conversion and processing is added. In the case of the L2CAL crate, the L1 input signals arrive in the form of fiber-optic cables. A special converter card (*Fiber Input Converter*, or FIC) translates optical signals into electrical signals (79).

B.2   Level 2 Alpha Processors

The overall design of the Alpha Board (Figure 102, Reference (80)) is based on the layout of the DEC [1] PC164 motherboard (81). It features a 500 MHz Alpha CPU running under real-time Linux. In addition to the internal PCI bus several elements supporting VME and MBus interfaces have been added. Figure 103 shows a schematic view of the Alpha Board. The main components are described in the following.

B.2.1   PC164 Based Design

The Alpha Board uses the first commercially available 64-bit RISC processor: a 500 MHz Alpha 21164 CPU (82; 83). It can execute 2-4 instructions per cycle. The 500 MHz CPU

[1]Digital Equipment Corp. merged with Compaq Computer Corp. in 1998.

Figure 101. Layout of Level 2 calorimeter (L2CAL) crate with main components.

frequency is generated by a 50 MHz oscillator by means of a divide-by-10 phase-locked loop circuit.

The Alpha Board has several caches implemented, both on-chip (integrated into the CPU) and external. 8 kB data and instruction caches (Dcache and Icache, respectively) buffer the most frequently used data and instructions to speed up processing. A secondary on-chip 96 kB mixed data and instruction cache (Scache) is also used. A third level of external cache (4 MB) is not being utilized.

An interface between the CPU, main memory, and the PCI bus is provided by the 21172 Core Logic Chipset (Figure 104, Reference (84)). The 21172 Chipset consists of the 21172-CA chip (CIA) which provides the interface between the CPU and the PCI bus. It also provides
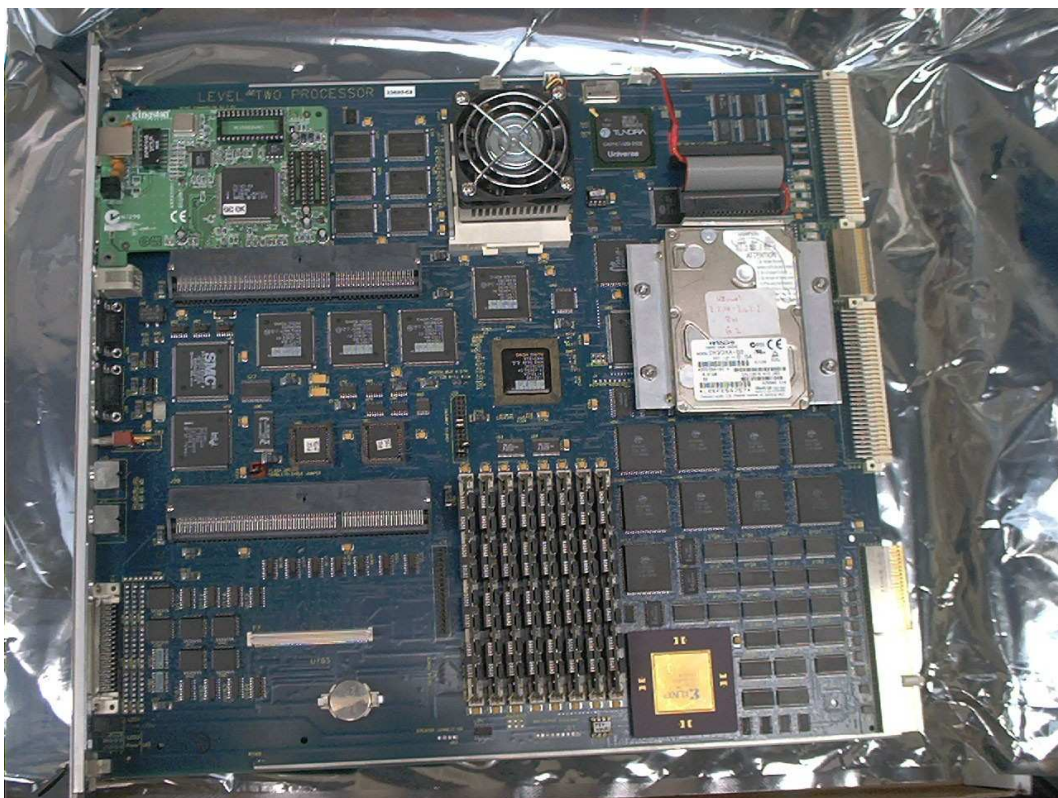

Figure 102. Level 2 Alpha Board with Ethernet card and hard disk drive.

Figure 103. Block diagram of Level 2 Alpha Board.

main memory controlling and addressing capabilities. A set of four data switching chips (DSW)

functions as a multiplexing/demultiplexing device for main memory access. The 21172 Chipset

provides data transfer rate of up to 267 MB/s (64-bit at 30 ns/cycle).

The Alpha Board carries two kinds of firmware. A 128 kB SROM chip is directly connected

to the Icache. It contains the boot code that is loaded into the CPU at power-up, including the

initialization of the PCI bus, the setting of registers in the CIA, the setting up of the various

caches and memory, and finally the copying of the contents of the Flash ROM to memory. The

1 MB Flash ROM chip contain OS and task specific instructions. This includes instructions to

download user code via a PCI Ethernet card, a rudimentary local debugger ("Debug Monitor"),

and the server for a remote debugger. The SROM chip is installed in a socket, and can therefore

be programmed by using an external device programmer. The Flash ROM chip is soldered to the board, and must be programmed in situ.

A bank of eight SIMM slots provides 128 MB of DRAM memory.

The 64-bit 33 MHz PCI bus has two expansion slots. A standard PCI Ethernet card connected to one of the PCI slots is used for remote access. Two programmable chips (PLDs) are used for PCI interrupt handling and bus arbitration.

A PCI-IDE interface chip connects a 6 GB IDE hard disk drive, which has real-time Linux installed.

A PCI-ISA bridge provides support for external devices such as a mouse, keyboard, and floppy drive. It also supports a parallel port, two serial ports, and a real time clock. The ISA bus is used to access the Flash ROM.

B.2.2   Magic Bus Programmed Input/Output

An interface between MBus and PCI bus is provided by the Magic Bus Programmed I/O chip (MBusPIO). It reads and writes data between the two address spaces and thereby provides a way of communication between different cards that are connected to the MBus. For example, a board connected to the MBus can write or read into Alpha Board memory. A programmable Xilinx XC4036EX chip (MAGICFPGA) is used for this task.

B.2.3   Magic Bus Direct Memory Access Interface

In order to boost processing time, data is transferred to and from Alpha Board memory by direct memory access (DMA), i.e. data on the MBus goes directly to Alpha Board memory
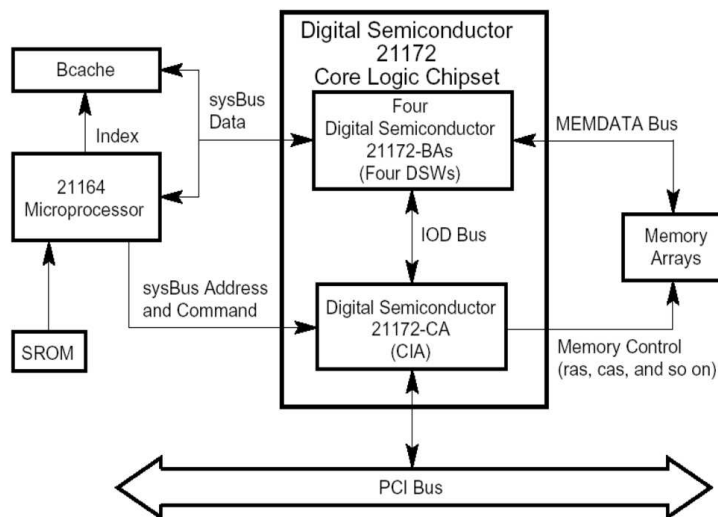

Figure 104. Block diagram of the 21172 Core Logic Chipset.

without involving the CPU. This *DMA engine* is implemented in two programmable chips: a Xilinx FPGA, and a Cypress CPLD.

B.2.4 VME Interface

A 64-bit PCI-VME interface is provided by the Tundra Universe II chip by mapping "windows" of VME address space to Alpha Board memory space (85).

B.2.5 TSI Interface

The TSI interface is used to receive and send additional information to the trigger system. Is is also used to monitor the state of the Alpha Board processing elements.

VITA

Marc Buehler was born in Rheinfelden, Germany on March 2, 1970. He grew up in Rhein-felden where he attended public school. In 1992 he earned a B.S. in Astronomy from the University of Basel, Switzerland. In 1997 he received a M.S. in Physics from the University of Heidelberg, Germany. He was accepted into the graduate physics program at the University of Illinois at Chicago, USA in 1997. Under the direction of Dr. Nikos Varelas, he received the degree of Doctor of Philosophy in Physics in 2005.
